20   **Abstract**

21   Cu, Fe and V oxides supported on N-TiO$_2$ (Cu/N-TiO$_2$, Fe/N-TiO$_2$, and V/N-TiO$_2$) were

22   synthetized by incipient wet impregnation method. The prepared photocatalysts were analyzed by

23   N$_2$ adsorption at -196°C to measure the specific surface area (S$_{BET}$) values, scanning electron

24   microscopy (SEM), wide-angle X-ray diffraction (WAXD), X-ray photoelectron spectroscopy

25   (XPS), Raman, photoluminescence and ultraviolet-visible diffuse reflectance (UV-vis DRS)

26   spectroscopies. The prepared photocatalysts were tested in the hydroxylation of benzene to phenol

27   under visible light irradiation in the presence of H_2O_2 as the oxidant. After 360 min of irradiation,

28   Cu/N-TiO$_2$ achieves a phenol yield equal to 25%, significantly higher than that observed with Fe/N-

29   TiO$_2$ (2%) and V/N-TiO$_2$ (2.5%). Moreover, Cu/N-TiO$_2$ photocatalyst exhibited a phenol yield

30   higher than that reported in the literature dealing with TiO$_2$ based photocatalysts for photocatalytic

31   benzene hydroxylation. The better photoactivity of Cu/N-TiO$_2$ in phenol production was justified

32   by considering both electronic and surface photocatalyst features. In detail, a significant optical

33   absorption in the visible region has been highlighted, due to the intense electronic interactions

34   between CuO and N-TiO$_2$. Moreover, the surface of the copper oxide component shows low affinity

35   with phenol molecules. Therefore, once photocatalytically generated, phenol easily desorbs from

36   the Cu/N-TiO$_2$ surface thus limiting parasitic overoxidation reactions. In fact, after 180 min of

37   visible light irradiation, only 30% of phenol was degraded by Cu/N-TiO$_2$, while 100% and 81% of

38   it was degraded by Fe/N-TiO$_2$ and V/N-TiO$_2$, respectively. From the comparison of phenol

39   production kinetic constants, obtained by fitting the experimental data with the least-squares

40   methods, showed that the highest rate of phenol formation ($k=1.41 \cdot 10^{-3}$ min^{-1}) was obtained by

41   using the Cu/N-TiO$_2$ photocatalyst. Cu/N-TiO$_2$ has been recovered from the aqueous solution after

42   a photocatalytic run and reused four times with no reduction in benzene conversion and phenol

43   yield, thus confirming the high stability of the catalytic system.

1.   Introduction

Phenol is currently produced through the 3-steps cumene process, which starts from benzene, and suffers drawbacks such as high energy consumption, low yields (ca. 5%), dangerous intermediates, such as cumene hydroperoxide, and the generation of acetone as a by-product, which strongly limits the market price [1-3]. Therefore, the direct hydroxylation of benzene would be a greener alternative to produce phenol, not only to reduce the hazardous nature of the cumene process, but also in terms of mass economy [4]. Heterogeneous photocatalysis is recognized as an innovative and green technology because it can be carried out under mild operating conditions, and in the presence of cheap and non-toxic semiconductors acting as photocatalysts activable by solar or artificial light with low-energy consumption [5]. The majority of photocatalytic processes, both for the degradation of organic compounds and for the synthesis of organic products, are based on photoinduced charge transfer, which occurs at the interface of the semiconductor, being the photogenerated electrons and holes, respectively, primary reducing and oxidizing agents [6-8]. Photocatalytic reactions are commonly performed under UV light [9], but suitable photocatalytic systems can also be activated by low-energy visible light, making available a powerful and sustainable route for organic synthesis and the production of valuable chemical compounds [10]. However, photocatalysis also presents some drawbacks, such as the low selectivity towards the partial oxidation products, especially by using water as the solvent [5, 11]. In the field of chemical reactions, it is certainly of research interest to find strategies to perform organic syntheses in a single step, and to control the reaction path in order to improve the selectivity towards the desired product, assuring its separation and recovery. The photocatalytic hydroxylation of benzene to phenol is an interesting example of green organic synthesis. Phenol is a chemical widely used as a disinfectant and as a precursor for the production

70   of resins and pharmaceutical products. However, the application of photocatalytic benzene

71   hydroxylation at an industrial level is limited by its fast kinetics, which makes the process highly

72   non-selective.

73   This problem has been successfully faced by coupling photocatalysis with a membrane separation

74   unit [12]. In general, this combined approach is useful for many other photocatalytic organic syntheses

75   of high-added value compounds [13] as it allows to separate the target compound from the reacting

76   mixture. However, the optimization of the intrinsic photocatalyst features remains a necessary step,

77   in order to design effective processes capable of competing with existing industrial processes. In

78   detail, the modification of the physical and chemical properties of the photocatalysts, for example

79   by coupling together different semiconductors, could be a possible strategy to improve the

80   efficiency and selectivity of the photocatalytic oxidation of benzene [5]. Each photocatalyst must be

81   optimized and selected for specific organic synthesis reactions since the selectivity control depends

82   on the molecular structure and properties of the organic substrate and its specific interaction with

83   the photocatalyst. In-depth studies are required to unveil the relationship between the surface

84   properties of the catalyst and substrate molecules and to be able to control the typical overoxidation

85   that occurs during photohydroxylation of aromatic compounds, such as benzene. In detail, Park and

86   Choi studied the photocatalytic conversion of benzene into phenol and showed the possibility of

87   increasing the phenol yield and selectivity by adding Fe^{3+} or/and H_2O_2 to the TiO_2 suspension or by

88   modifying the surface of the catalyst by deposition of Pt nanoparticles [14]. Ide et al. formulated a

89   layered titanate photocatalyst decorated with gold nanoparticles, which catalyzed the oxidation of

90   aqueous benzene to phenol under visible light irradiation. Moreover, it was found that the reaction

91   efficiency was improved when the oxidation was performed with the addition of phenol into the

92   starting mixture, by leading to an appreciable increase in yield and selectivity [15]. Devaraji et al.

93   demonstrated that the introduction of vanadium into the TiO_2 lattice, and the photodeposition of

94   gold on the photocatalytic surface increased the benzene conversion and selectivity to phenol [16].

95   The liquid-phase hydroxylation of benzene to phenol was also investigated by Tanarungsun et al. in

96   the presence of transition metals (copper, vanadium, iron) impregnated on a TiO_2 support,

97   demonstrating a higher phenol yield obtained with the impregnated TiO_2 systems under UV light

98   compared to bare TiO_2 [17]. Based on the results reported in the literature and considering our

99   preliminary results on N-doped TiO_2 photocatalyst [18], in this work transition metal oxides (iron,

100   vanadium and copper oxide) were supported on N-TiO_2 and tested in the hydroxylation of benzene

101   to phenol under visible light.

102

103   **2. Materials and methods**

104   **2.1 Chemicals and reagents**

105   Benzene (purity>99.7%) and cyclohexane (purity>99%) were purchased from Sigma Aldrich.

106   Distilled water and acetonitrile (purity>99.9%) were acquired from Carlo Erba. Hydrogen peroxide

107   solution used as oxidant was purchased from Sigma Aldrich (30 wt%). Titanium(IV) isopropoxide

108   (purity>97%), copper nitrate trihydrate, iron nitrate nonahydrate and ammonium metavanadate

109   were provided by Sigma Aldrich.

110

111   **2.2 N-doped TiO_2 preparation**

112   N-doped TiO_2 (N-TiO_2) photocatalyst was synthesized by sol-gel method using ammonia solution

113   (30 wt%), as nitrogen source, and titanium isopropoxide. The preparation was carried out according

114　to the procedure reported by Sacco et al. [19]. Briefly, the synthesis of $N-TiO_2$ was carried out at 0 °C

115　until the formation of a precipitate, which washed using distilled water and finally calcined at

116　450°C for 30 min. The N/Ti nominal molar ratio used in the photocatalyst preparation was equal to

117　18.6 [19].

118

119　**2.3 Preparation of transition metal oxides loaded on N-TiO₂ photocatalyst**

120　Cu, Fe and V oxides loaded on $N-TiO_2$ (named $Cu/N-TiO_2$, $Fe/N-TiO_2$, and $V/N-TiO_2$) were

121　prepared by the incipient wet impregnation method [20]. 1 g of $N-TiO_2$ powder was suspended in 100

122　mL of aqueous solutions containing the appropriate amount of trihydrate copper nitrate (0.23 g),

123　nonahydrate iron nitrate (0.38 g) or ammonium metavanadate (0.11 g) in order to obtain

124　photocatalysts with a loading of each metal equal to 5 wt%, as considered in literature [17]. The

125　suspensions were dried at 120°C for 12 h and the obtained powders were finally calcined in a

126　muffle oven at 450°C for 30 min.

127

128　**2.4 Photocatalyst characterization techniques**

129　Wide-angle X-ray diffraction (WAXD) patterns were obtained with an automatic Bruker D8

130　Advance diffractometer (VANTEC-1 detector) using reflection geometry and nickel filtered Cu-Kα

131　radiation. The average crystallite size of the synthesized powders was calculated using the Scherrer

132　equation [21]. The Brunauer-Emmett-Teller (BET) surface area of the samples was measured from

133　dynamic N_2 adsorption measurement at -196 °C, performed by a Costech Sorptometer 1042 after a

134　pre-treatment for 30 min in He flow at 150 °C.

135   Laser Raman spectra were attained at room temperature with a Dispersive MicroRaman (Invia,

136   Renishaw), equipped with 514 nm laser, in the range 100 - 2000 cm^{-1} Raman shift.

137   The ultraviolet-visible diffuse reflectance spectra (UV-Vis DRS) of the samples were obtained

138   using a Perkin Elmer spectrometer Lambda 35 spectrophotometer equipped with a RSA-PE-20

139   reflectance spectroscopy accessory (Labsphere Inc., North Sutton, NH). The indirect band gap

140   values of samples were obtained through the corresponding Kubelka–Munk function ($F(R_\infty)$) and by

141   plotting $[F(R_\infty)\cdot h\nu]^{1/2}$ vs $h\nu$ (eV) [22, 23].

142   X-ray photoelectron spectroscopy (XPS) characterization of the catalysts' surface was performed on

143   a PHI Versaprobe II spectrometer using monochromatized Al-Kα source (47.6 W) at constant

144   charge neutralization with a 200 μm spot size. Spectra were acquired on at least three points of the

145   samples and processed with ULVAC-PHI MultiPak® (v. 9.9.3) software. The Binding Energy (BE)

146   scale was calibrated setting the aliphatic component of C1s at 284.8 eV. Energy pass was set at

147   46.95 eV for high-resolution (HR) spectra.

148   Fluorescence spectra of the powders were recorded by suspending them in cyclohexane and by

149   using a Jasco FP-6300 spectrofluorimeter (Jasco, Tokyo, Japan) with λ= 325 nm as the excitation

150   wavelength. Field emission scanning electron microscopy (FE-SEM) analysis was carried out by

151   means of FE-SEM, Supra 40/40VP equipped with an EDAX probe (Zeiss, Oberkochen, Germany),

152   operating at a voltage of 20 kV on specimens where a 6 nm thin layer of Pt/Pd had been deposited

153   under Ar atmosphere.

154

155

156

2.5 Photocatalytic activity tests

The benzene hydroxylation reaction was performed in 200 mL aqueous solution containing benzene (initial concentration: 25.6 mmol/L) and acetonitrile (2.3 mL) as a co-solvent with 0.15 g/L of Cu/N-TiO$_2$, Fe/N-TiO$_2$, and V/N-TiO$_2$ photocatalyst under continuous stirring in a cylindrical Pyrex photoreactor. 2.8 mL of H$_2$O$_2$ (30 wt% in H$_2$O) were added to the reaction mixture (H$_2$O$_2$ concentration: 136 mmol/L).

The system was first kept under dark for 60 min at room temperature, to reach the adsorption-desorption equilibrium of benzene. Then, the reactor was irradiated for 600 min by a LEDs strip emitting visible light (emission range: 400–800 nm; irradiance: 16 W/m^2) placed around and in contact to the external surface of the Pyrex reactor. A fan cooled down the reactor during irradiation time. Solution aliquots were withdrawn from the reactor at different times by a 1 mL syringe, filtered through a 0.22 µm CA filter (SIMPLEPURE) to remove solid particles, and immediately analyzed quantitatively by an Agilent gas chromatograph (model 7820 A) equipped with a flame ionization detector (FID) to evaluate the benzene and phenol concentration. Some photocatalytic tests were carried out using 100 mL of phenol (initial concentration: 0.53 mmol/L) aqueous solution, 0.15 g/L of photocatalyst and H$_2$O$_2$ concentration equal to 136 mmol/L. GC separation was achieved with a DB Heavy Wax fused-silica capillary column (30m x 0.35mm i.d. x 0.25µm stationary phase thickness) under the following conditions: column temperature 40-300°C (40°C held 2 min, rate 5°C/min to 90°C, rate 20°C/min to 250°C, held 10 min); helium at a constant flow rate of 1 mL/min; injection port operated at 10:1 split mode; the temperature of injector and detector at 180°C and 300°C, respectively. Hydroquinone, resorcinol, p-benzoquinone and catechol were determined quantitatively by HPLC, using a Dionex UltiMate 3000 Thermo Scientific system

179   equipped with DAD detector, column thermostat and automatic sample injector with 100μL loop.

180   Separations were carried out on a Phenomenex Luna C-18 column (150 x 4.6 mm i.d.; 5μm) eluted

181   with a mixture of water (solvent A) and acetonitrile (solvent B) according to the program: 0-14 min,

182   15% B (isocratic); 14-23 min, 60-100% B (linear gradient); 23-30 min, 15% B (isocratic). The

183   chromatographic conditions were: oven temperature 35°C; flow rate 0.8 mL/min; injection volume

184   50 μL and UV detector at 270 nm. Benzene conversion (Bz_{conv}), yield (Y_P) and selectivity (S_P)

185   towards phenol and by-products were evaluated according to Eqs. 1-3.

186      $benzene\ conversion\ (Bz_{conv}) = \left(1 - \frac{C}{C_0}\right) x\ 100$ 　　　　　　　　　　　　　　　(1)

187      $yield\ to\ P\ (Y_P) = \left(\frac{S}{Q_0}\right) x\ 100$ 　　　　　　　　　　　　　　　　　　　(2)

188      $selectivity\ to\ P\ (S_P) = \left(\frac{S\ (or\ Deg)}{S_{TOT}\ + Deg}\right) x\ 100$ 　　　　　　　　　　　　(3)

189   Where:

190   C_0 = benzene concentration after the dark period (mmol/L);

191   C = benzene concentration at the generic irradiation time (mmol/L);

192   Q_0 = moles of benzene in solution after the dark period (mmol);

193   P = reaction product (phenol or hydroquinone or catechol or resorcinol or p-benzoquinone);

194   S_{TOT} = total moles of the reaction products in liquid phase detected by HPLC (mmol);

195   S = moles of phenol or hydroquinone or catechol or resorcinol or p-benzoquinone in liquid phase
196   (mmol);

197   D_{eg}= ring-opened products and CO_2 = (benzene reacted$-S_{TOT}$) [24].

198

199

3. Results and discussion

3.1 Photocatalysts characterization results

FE-SEM images of the Cu, Fe and V oxides supported on N-TiO$_2$ samples are shown in Figure 1, along with Cu, Fe and V atoms EDX maps.

Figure 1. SEM images of Cu/N-TiO$_2$ (a), Fe/N-TiO$_2$ (b), and V/N-TiO$_2$ (c) samples along with the correspondent Cu (a'), Fe (b'), and V (c') atoms maps.

Green Chemistry

208 The three mixed oxide catalytic systems show a similar micrometric aggregate morphology. Cu, Fe

209 and V atoms are homogeneously distributed throughout the samples and their normalized atomic

210 weight percent is 5.9, 5.5 and 3.3%, respectively.

211 The crystalline phase structure of all the samples was identified by wide-angle X-ray diffraction

212 (WAXD) (Figure 2). The WAXD patterns of all the synthesized samples showed the typical signals

213 of TiO_2 anatase crystalline phase [25]. The peaks were located at the 2θ values of 25.3, 37.8, 48.1,

214 53.9, 55.1, 63.1 and 69.2° and they correspond to (101), (004), (200), (105), (211), (204) and (116)

215 anatase lattice planes [26]. However, the diffraction pattern of the $N-TiO_2$ sample evidenced a weak

216 diffraction peak at 27° that could be attributed to the presence of TiO_2 in the rutile crystalline phase

217 [27]. The peak at 38° related to Fe_2O_3 is not revealed for $Fe/N-TiO_2$ as also reported in the literature

218 for similar systems [17], probably because the loading of Fe (nominally 5% wt) is below the detection

219 limit of the instrument. A similar result was obtained for $V/N-TiO_2$. Also in this case, the absence of

220 further peaks belonging to the V_2O_5 orthorhombic phase is probably due to the low vanadium

221 loading. Conversely, the presence of peaks at 2θ = 35.2, 36.2 and 38.3°, corresponding to (110),

222 (002) and (111) CuO lattice planes (inset in Figure 2) [28, 29], is detected for the $Cu/N-TiO_2$ sample.
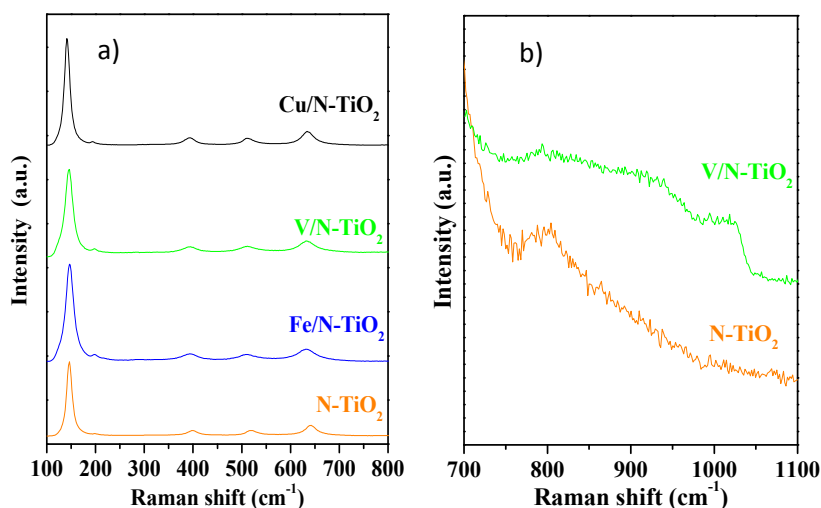

223

224
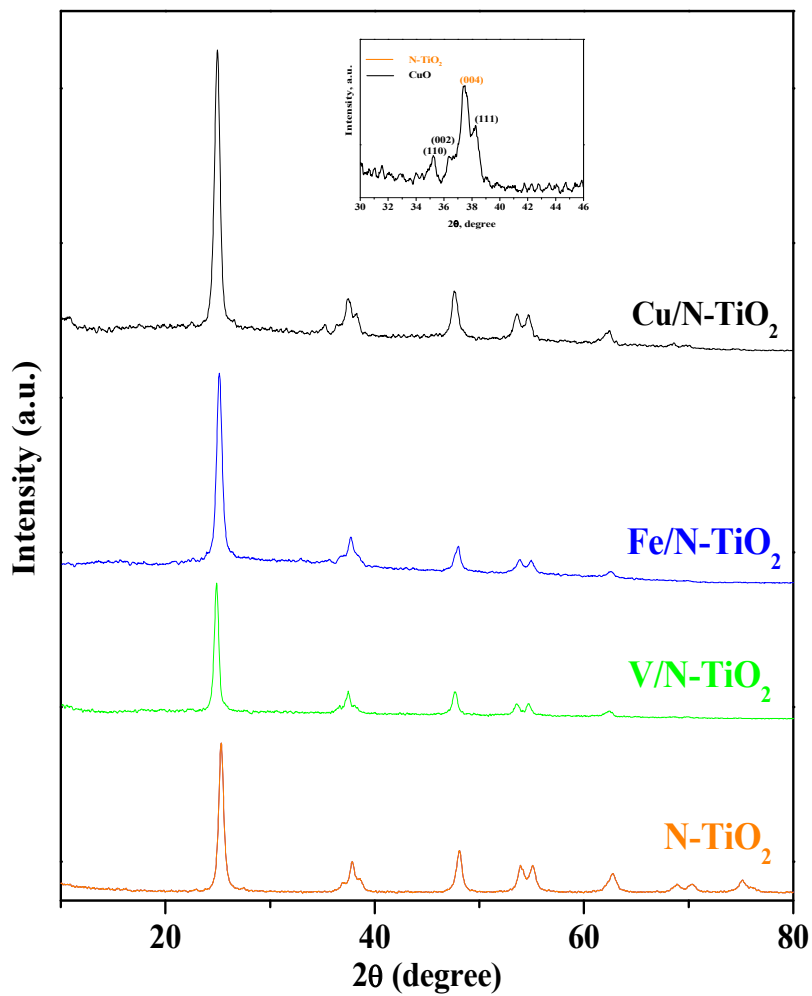

Figure 2. Wide angle X-ray diffraction (WAXD) patterns of N-TiO$_2$, Cu/N-TiO$_2$, Fe/N-TiO$_2$ and V/N-TiO$_2$ samples.

The Raman spectra of N-TiO$_2$, Cu/N-TiO$_2$, Fe/N-TiO$_2$ and V/N-TiO$_2$ samples are shown in Figure 3.

Figure 3. Raman spectra of N-TiO$_2$, Cu/N-TiO$_2$, Fe/N-TiO$_2$ and V/N-TiO$_2$ (a). Raman spectra of N-TiO$_2$ and V/N-TiO$_2$ in narrow Raman shift range 700-1100 cm^{-1}(b).

N-TiO$_2$ sample showed bands at 144, 397, 516 and 638 cm^{-1} and a weak shoulder at 195 cm^{-1}, due to the Raman-active fundamental modes of anatase [30]. Raman bands associated with CuO and Cu$_2$O, reported in literature at 279 and 216 cm^{-1}, respectively, were not observed [28, 31].

The Raman spectrum for the Fe/N-TiO$_2$ sample did not evidence bands related to iron oxides, such as Fe$_3$O$_4$ [32]. Conversely, Raman spectrum of V/N-TiO$_2$ in the narrow range 700-1100 cm^{-1} (Figure 2b) displayed a wide and not very intense band at about 940 cm^{-1}, assigned to the V-O-V functionality, indicating the presence of polyvanadate species. Furthermore, a Raman contribution to about 1016 cm^{-1} was observed for V/N-TiO$_2$ due to V-O-Ti functionality still assigned to polyvanadate dispersed on N-TiO$_2$ surface [33].

XPS analysis provided the surface chemical composition of N-TiO$_2$ and Cu, Fe and V oxides supported on N-TiO$_2$, as reported in Table 1. N-doping level in all mixed oxide catalytic systems was not affected by the surface deposition process being similar to the value obtained on pristine N-TiO$_2$ sample.

247   **Table 1.** Typical surface chemical composition in terms of atomic % of the as-prepared samples. Values are

248   expressed as the mean ± 1SD on three analysis points. M is the corresponding metal of Cu, Fe and V oxides.

Catalyst	C%	O%	Ti%	N%	M%
N-TiO$_2$	16.9±1.2	58.2±1.4	24.3±1.5	0.6±0.2	/
Cu/N-TiO$_2$	19.0±1.3	53.8±1.1	21.0±0.8	0.8±0.3	5.4±0.7
Fe/N-TiO$_2$	17.3±1.5	56.0±1.5	20.2±0.7	0.6±0.2	5.9±1.1
V/N-TiO$_2$	21.3±1.4	54.7±1.3	19.3±1.1	0.7±0.2	4.0±0.5

249

250   Peak position for Ti2p$_{3/2}$ was found at 458.7±0.1 eV, compatible with TiO$_2$ [34] (Figure S1 in

251   Supplementary Material). In general, oxide surface deposition processes seemed successful

252   considering the metal percentage on the surface. Analysis of Cu2p$_{3/2}$ HR region has shown that

253   copper is mainly present as Cu(I) (BE = 932.6±0.2 eV) and only 0.5% is ascribable to Cu(II) (BE =

254   934.5±0.2 eV) (Figure 4a) [34]. V2p$_{3/2}$ component in V2p region (Figure 4b) was fitted with a minor

255   peak at BE = 515.9±0.2 eV, typical of V^{3+}/V^{4+}, and the main at BE = 517.0±0.2 eV attributed to

256   V$_2$O$_5$ indicating the possible presence of polyvanadates [35]. Fe speciation by XPS analysis is more

257   difficult though Fe2p$_{3/2}$ position at about 710.7 eV is compatible with Fe(III) species (such as Fe$_2$O$_3$

258   or FeOOH), similar to other reported photocatalysts [36, 37], but the presence of Fe(II) cannot be

259   excluded (Figure S2 in Supplementary Material).
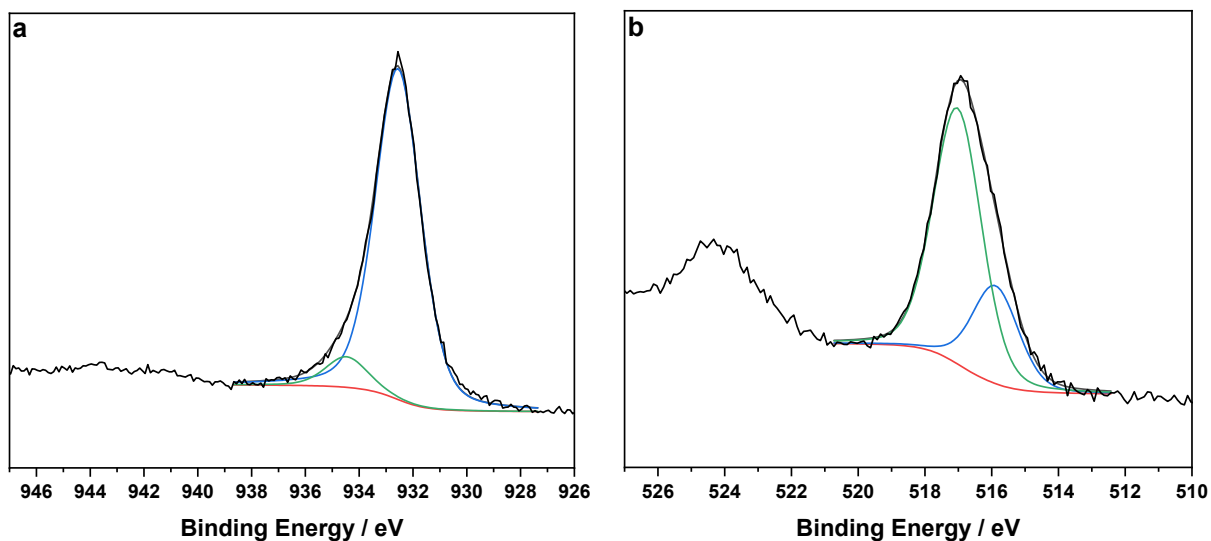

Figure 4. Typical Cu2p$_{3/2}$ spectrum relevant to Cu/N-TiO$_2$ samples (a); V2p region relevant to V/N-TiO$_2$ powders (b).

The fluorescence spectra of all the photocatalysts are reported in Figure 5.

266 **Figure 5.** Fluorescence spectra of N-TiO$_2$ (black line), Cu/N-TiO$_2$ (red line), Fe/N-TiO$_2$ (blue line), and
267 V/N-TiO$_2$ (green line) samples dispersed in cyclohexane. The dashed spectrum is the signal acquired in the
268 presence of neat cyclohexane. All of the spectra have been normalized with respect to this signal. Excitation
269 wavelength: 325 nm.
270

271 N-TiO$_2$ sample shows a broad emission band with well-resolved emission features centered at 386,

272 409, and 431 nm. The signal at 386 nm has been assigned to band-to-band recombination of TiO$_2$

273 anatase phase [38, 39]. Peaks at 409 and 431 nm can be assigned to emission originating from intra-

274 band gap energy states related to oxygen vacancies or nitrogen sites, according to the relevant

275 literature [40-42]. Notably, the signal at 409 nm is also consistent with band-to-band emission of TiO$_2$

276 rutile phase [43], which is present in traces according to WAXD analysis. All of the mixed oxide

277 catalytic systems show lower emission with respect to N-TiO$_2$ sample, thus indicating lower charge

278 recombination possibly due to interfacial electron transfer between the component oxides, resulting

279 in improved spatial charge separation and longer lifetime of the photogenerated charges [44-46].

280 The BET specific surface area (S$_{BET}$) and the anatase average crystallite size of the samples

281 (calculated by using the Scherrer equation) are reported in Table 2. Cu/N-TiO$_2$ and Fe/N-TiO$_2$

282 showed an S$_{BET}$ lower than that of the N-TiO$_2$ sample. This result is in agreement with the higher

283 crystallite size of these two samples with respect to the value observed for the N-TiO$_2$

284 photocatalyst.

285 The optical properties of the photocatalysts have been investigated by evaluating their band gap

286 energy according to the Kubelka-Munk theory, assuming that they are indirect semiconductors. In

287 order to highlight the extent of the electronic interaction between the component oxides, the same

288 analysis has been carried out on mechanical mixtures of the oxides by using the same weight

289 percent of the synthesized powders. Results are reported in Figure 6.

16

290	Firstly, it is worth mentioning that the N-TiO$_2$ sample exhibits improved optical properties in the

291	visible region (Figure 6) with a reduction of band-gap value (E$_{bg}$) from 3.20 eV (the typical band-

292	gap of undoped TiO$_2$) [47] to 2.25 eV (Table 2). The narrow band-gap value of N-TiO$_2$ is attributed to

293	the presence of nitrogen in the TiO$_2$ lattice [19]. The synthesized mixed oxide catalytic systems show

294	E$_{bg}$ values lower than N-TiO$_2$ (Table 2) due to the contribution of the transition metal oxides (both

295	band-to-band and d-d transitions occurring in the visible light range) loaded onto the N-TiO$_2$

296	sample. By comparing the Tauc plots of the synthesized mixed oxide samples with those of the

297	mechanical mixtures, it is possible to observe a red shift of the absorption edge for all of the

298	synthesized mixed oxide samples, which is particularly relevant for the Cu/N-TiO$_2$ one.

299	This behavior has been already reported in the relevant literature for strongly interacting electronic

300	systems, in which an extended alteration of the electronic structure of the mixed phase with respect

301	to the components can be observed. This is reported for instance in vanadium, chromium, iron or

302	nickel-doped TiO$_2$ prepared by ion implantation [48], for GaN–ZnO solid solutions [49], and for mixed

303	ZnO-Fe$_2$O$_3$ photocatalysts [50].

304	The red shift observed in the synthesized mixed oxide samples with respect to the mechanical

305	mixtures may due to a strong interaction between N-TiO$_2$ and the oxides dispersed on its surface. In

306	particular, for TiO$_2$–Fe$_2$O$_3$ systems the effective mixing between the surface Fe^{3+} and O2p levels,

307	due to the Ti–O–Fe interfacial bond yielding surface sub-bands, has been reported [51]. A similar

308	mechanism can be inferred in the case of V/N-TiO$_2$ and Cu/N-TiO$_2$ samples. However, in the Cu/N-

309	TiO$_2$ case the red shift of the absorption edge is ca. three times higher with respect to the other

310	samples, thus indicating a stronger electronic interaction between the component oxides, and an

311	improved visible light absorption capability.

312

333   **3.2 Photocatalytic activity results**

334   **3.2.1 Visible light-driven benzene hydroxylation with Cu/N-TiO$_2$, Fe/N-TiO$_2$ and V/N-TiO$_2$**

335   **photocatalysts**

336   It is worth pointing out that N-TiO$_2$ photocatalyst showed a high benzene conversion (62%) without

337   phenol formation, as already reported in previous studies[18]. Therefore, the visible light-driven

338   benzene oxidation was performed using Cu/N-TiO$_2$, Fe/N-TiO$_2$ and V/N-TiO$_2$ photocatalysts in

339   order to test the possibility of providing higher selectivity towards phenol. The benzene relative

340   concentration and phenol yield as a function of run time with Cu/N-TiO$_2$, Fe/N-TiO$_2$ and V/N-TiO$_2$

341   photocatalysts are reported in Figure 7.

353   **Figure 7**. Benzene relative concentration and phenol yield as a function of run time, in dark (up to the dotted
354   line) and under visible light, using Cu/N-TiO$_2$ (a), Fe/N-TiO$_2$ (b) and V/N-TiO$_2$ (c) photocatalysts. Phenol
355   yield as a function of visible irradiation using Cu/N-TiO$_2$, Fe/N-TiO$_2$ and V/N-TiO$_2$ photocatalysts (d).
356

357   In the absence of visible light (dark condition), benzene is adsorbed on Cu/N-TiO$_2$ surface for

358   almost 50% in 30 min (Figure 7a). Despite the presence of H$_2$O$_2$ as oxidant, phenol was not

359   produced under dark conditions, indicating that no direct H$_2$O$_2$-mediated oxidation occurred. When

360   visible LEDs were switched on, benzene was converted and, consequently, its relative concentration

361   decreased with irradiation time (Figure 7a). Phenol yield gradually increased during irradiation

362   time, reaching a maximum value of 25% after 360 min of irradiation, and then it decreased up to a

363   value of 19% at the end of the test (600 min of visible light). Fe/N-TiO$_2$ photocatalyst adsorbed

364   benzene for about 46% after 30 min in dark condition (Figure 7b). As the reactor was irradiated

365   with visible LEDs, the reaction has begun, the benzene was converted and the phenol yield was 2%

366   at the end of the test (600 min of visible irradiation). Similarly, V/N-TiO$_2$ adsorbed benzene in the

367   dark up to 36% (Figure 7c) and, when the photoreaction started, a progressive decrease of benzene

368   relative concentration could be observed providing a phenol yield of about 2.5% after 600 min of

369   irradiation time. For the sake of comparison, Figure 7d shows the phenol yield as a function of

370   irradiation time obtained with Cu/N-TiO$_2$, Fe/N-TiO$_2$ and V/N-TiO$_2$ samples. It is evident that the

371   maximum yield obtained in the presence of the Cu/N-TiO$_2$ sample (25%) was remarkably higher

372   than that obtained in the presence of the Fe/N-TiO$_2$ (2%) and V/N-TiO$_2$ (2.5%) samples.

373   Table 3 summarizes the values of benzene conversion, and yield and selectivity towards phenol and

374   other oxidation products in the presence of N-TiO$_2$ alone and coupled with the three considered

375   oxides.

376
377

21

378
379 **Table 3.** Benzene conversion, selectivity to phenol and CO_2 and other ring-opened compounds, yield to
380 phenol, hydroquinone, catechol and resorcinol obtained using N-TiO_2, Cu/N-TiO_2, Fe/N-TiO_2 V/N-TiO_2
381 powder after 600 min of visible light irradiation.

Catalyst	Bz_{conv}	Y_{phenol}	$Y_{hydroquinone}$	$Y_{catechol}$	$Y_{resorcinol}$	$Y_{p\text{-}benzoquinone}$	S_{phenol}	S_{Deg}
N-TiO$_2$	62%	n.d	<1%	n.d	n.d	n.d	n.d	>98%
Cu/N-TiO$_2$	82%	19%	2%	11%	<1%	5%	23%	63%
Fe/N-TiO$_2$	94%	2%	<1%	n.d	n.d	<1%	2%	97.4%
V/N-TiO$_2$	71%	2.5%	<1%	<1%	n.d	<1%	3.5%	96.3%

382

383 The conversion values obtained in the presence of the three mixed oxides catalytic systems are

384 roughly similar, ranging between 71 and 94%. This agrees with the results of photoluminescence,

385 which show similar suppression of fluorescence for all of the samples, suggesting an efficient

386 spatial charge separation taking place at the interface between the component oxides, as reported in

387 the relevant literature for similar systems[52]. However, phenol selectivity and yield using Cu/N-TiO$_2$

388 are higher than those obtained with Fe/N-TiO$_2$ and V/N-TiO$_2$ under visible light. The phenol yield

389 achieved with Cu/N-TiO$_2$ was higher than that observed with TiO$_2$-based photocatalysts reported in

390 the literature (Table 4). Indeed, under UV light, in most cases the phenol yield was in the range

391 0.76-16%, lower than that of Cu/N-TiO$_2$ photocatalyst (25% after 360 min of visible light

392 irradiation). A phenol yield equal to 25.2% was observed on TiO$_2$ modified with iron and cromium

393 but after 12 h of reaction time and with a benzene conversion (28%)[53] lower that that achieved with

394 Cu/N-TiO$_2$ (82 % after 600 min of visible light irradiation). It is worth noting to underline that the

395 literature about the visible-light driven hydroxylation of benzene to phenol in presence of TiO$_2$

396 based photocatalysts is still scarce.

397

Table.4 Comparison with literature papers dealing with different photocatalysts for benzene hydroxylation.

To explain the higher phenol selectivity and yield achieved with the copper-based photocatalyst, the activity of $Cu/N-TiO_2$, $Fe/N-TiO_2$ and $V/N-TiO_2$ photocatalysts was tested for phenol degradation under visible light as described in the experimental part. Results are reported in Figure 8 along with the adsorption percentage of phenol under dark conditions, for each photocatalytic sample. Notably,

405 as reported in the literature, under the same experimental conditions, N-TiO$_2$ leads to 77% phenol

406 degradation after 180 min visible light irradiation [56]. However, Figure 8 shows that Fe/N-TiO$_2$ was

407 the photocatalyst capable of completely degrading phenol. On the contrary, Cu/N-TiO$_2$ was the less

408 active photocatalyst in the phenol degradation, achieving a very low degradation efficiency of

409 phenol equal to 30% after 180 min of visible light irradiation. A similar trend is apparent as far as

410 the dark adsorption results are concerned. In fact, phenol adsorption under dark conditions is

411 negligible in the presence of Cu/N-TiO$_2$, while it reaches values of 10 and 20% for V/N-TiO$_2$ and

412 Fe/N-TiO$_2$, respectively. By summarizing, while all the three mixed oxides catalytic systems show a

413 similar benzene conversion (Figure 7a, b and c), marked differences among them arise as far as the

414 phenol degradation and dark adsorption are concerned, which follows the order Fe/N-TiO$_2$ > V/N-

415 TiO$_2$ > Cu/N-TiO$_2$ (Figure 8). An opposite trend is observed when considering the selectivity

416 towards phenol, which is, instead, the highest for the Cu/N-TiO$_2$ photocatalyst. These results can be

417 justified by considering the almost negligible interaction between phenol and the surface of Cu/N-

418 TiO$_2$ in agreement with the dark adsorption results. Once photocatalytically generated, therefore, the

419 overoxidation of phenol is limited by its favored desorption from the surface of the photocatalyst,

420 thus resulting in its accumulation in the reaction medium. Notably, as often reported for similar

421 photocatalytic systems, also in the case of phenol degradation an inverse relationship between

422 oxidizing capability and selectivity can be observed [57], as a result of the peculiar interaction

423 between a target compound and the surface of the photocatalyst. Therefore, also for the present

424 photocatalytic system, surface phenomena play a key role in determining the selectivity of a

425 photocatalytic reaction [58].
Figure 8. Phenol degradation efficiency after 180 min of visible light irradiation using Cu/N-TiO$_2$, V/N-TiO$_2$ and Fe/N-TiO$_2$ photocatalysts.

The stability trend of Cu/N-TiO$_2$ photocatalyst was confirmed by performing a series of consecutive photocatalytic oxidation tests in which, after each run, the material was recovered by centrifugation, dried at room temperature for 24 hours and reused in a new catalytic cycle. Based on this procedure, four reuse cycles were carried out under visible LEDs irradiation using the photocatalyst optimized in this work. As shown in Figure 9, no significant decrease in both benzene conversion and phenol

435   yield was observed in all the reuse cycles, proving the stability of the Cu/N-TiO$_2$ photocatalyst.
436

437   **Figure 9.** Benzene conversion and phenol yield after 360 min of visible light irradiation for different reuse
438   cycles using Cu/N-TiO$_2$ photocatalyst.

439

440   The WAXD analysis was performed on the Cu/N-TiO$_2$ recovered from the photoreactor after four

441   reuse cycles (Figure 10).

467

468 No substantial difference with respect to the WAXD spectrum of the catalyst before its use was

469 observed, confirming the stability of Cu/N-TiO$_2$ photocatalyst in the hydroxylation of benzene.

470

471 **3.2.3 Kinetic modelling of benzene hydroxylation using Cu/N-TiO$_2$, Fe/N-TiO$_2$ and V/N-TiO$_2$**

472 **photocatalysts**

473 The experimental data together with the concentration of by-products detected by HPLC analysis

474 (Figure S3 in Supplementary Material) were used for the kinetic modeling of the three mixed oxide

475 photocatalysts in order to calculate the phenol production kinetic constant for each photocatalytic

476 system.

477 The main problem of the benzene (BZ) hydroxylation to phenol (PhOH) is related to the

478 consecutive reactions, which lead to by-products such as hydroquinone (HQ), benzoquinone (BQ),

479 catechol (CT), resorcinol (RS) and other ring opening products and eventually CO_2. The identified

480 reaction paths are shown in Figure 11. When the benzene photocatalytic hydroxylation occurs using

481 Cu/N-TiO$_2$ photocatalyst, the production of all by-products can be observed according to the

482 reaction mechanism shown in Figure 11a. On the other hand, Fe/N-TiO$_2$ does not provide detectable

483 production of catechol (CT) and resorcinol (RS), suggesting that the route of addition of hydroxyl

484 groups to benzene takes place preferentially in the para position (Figure 11b). Instead, V/N-TiO$_2$

485 photocatalyst leads to the production of phenol and the other by-products, except resorcinol (Figure
486 11c).

507　Fe/N-TiO$_2$ (b) and V/N-TiO$_2$ (c).
508

509

510   More in detail, under visible light irradiation and in the presence of Cu/N-TiO$_2$, benzene is directly

511   hydroxylated to phenol and HQ. The oxidative conditions of the system lead to the conversion of

512   HQ to BQ, but the equilibrium reaction between these two species in the aqueous system cannot be

513   excluded, as reported in some literature papers [59]. On the other hand, the production of BQ may

514   occur from phenol, since the •OH radical is highly reactive [59-61]. The concentration of BQ and CA

515   reached appreciable values with respect to the HQ and RS concentration only with the Cu/N-TiO$_2$

516   photocatalyst. Therefore, it is hypothesized that CA and RS are produced by phenol hydroxylation

517   (Figure 11a).

518   Phenol and BQ can be produced by benzene in the presence of irradiated Fe/N-TiO$_2$, as shown from

519   HPLC analysis (see Supplementary Materials) and consistently with the literature dealing with the

520   oxidation of benzene in presence of copper-based catalysts [62, 63]. HQ can be formed from phenol.

521   Then, HQ is further oxidized to BQ. Also, in this case, the equilibrium reaction between HQ and

522   BQ cannot be excluded (Figure 11b). In the same reaction conditions with V/N-TiO$_2$ photocatalyst,

523   benzene is directly converted to phenol and HQ that can be further oxidized to BQ. HQ can be

524   produced from benzene and phenol. Consequently, phenol can give CA, HQ and can be directly

525   oxidized to BQ (Figure 11c).

526   Considering the reaction schemes proposed in Figure 11, a kinetic model for the photocatalytic

527   hydroxylation of benzene is developed, considering first-order kinetics for all the reactions involved

528   in the system [59] [. The mass balance equations for Cu/N-TiO$_2$ photocatalyst are given below:

529    $$\frac{dC_{Bz}}{dt} = -k_1 C_{Bz} - k_2 C_{Bz} \qquad (4)$$

530

531 $$\frac{dC_{PhOH}}{dt} = k_1 C_{Bz} - k_4 C_{PhOH} - k_7 C_{PhOH} - k_3 C_{PhOH} - k_{10} C_{PhOH} \qquad (5)$$

532

533 $$\frac{dC_{HQ}}{dt} = -k_5 C_{HQ} + k_2 C_{Bz} + k_7 C_{PhOH} + k_5' C_{BQ} - k_{11} C_{HQ} \qquad (6)$$

534

535 $$\frac{dC_{CT}}{dt} = k_3 C_{PhOH} - k_8 C_{CT} \qquad (7)$$

536

537 $$\frac{dC_{RS}}{dt} = k_4 C_{PhOH} - k_9 C_{RS} \qquad (8)$$

538

539 $$\frac{dC_{BQ}}{dt} = k_5 C_{HQ} - k_6 C_{Bz} - k_5' C_{Bz} + k_{10} C_{PhOH} \qquad (9)$$

540

541 $$\frac{dC_{CO_2}}{dt} = 6 * k_6 C_{BQ} + 6 * k_8 C_{CT} + 6 * k_9 C_{RS} + 6 * k_{11} C_{HQ} \qquad (10)$$

542

543

544   The mass balance equations for Fe/N-TiO$_2$ photocatalyst are reported below:

545 $$\frac{dC_{Bz}}{dt} = - k_1 C_{Bz} - k_2 C_{Bz} \qquad (11)$$

546

547 $$\frac{dC_{PhOH}}{dt} = k_1 C_{Bz} - k_3 C_{PhOH} \qquad (12)$$

548

549 $$\frac{dC_{HQ}}{dt} = k_3 C_{PhOH} - k_4 C_{HQ} + k_4' C_{BQ} \qquad (13)$$

550

551 $$\frac{dC_{BQ}}{dt} = k_2 C_{BZ} - k_5 C_{BQ} + k_4 C_{HQ} - k_4' C_{BQ} \qquad (14)$$

552

553 $$\frac{dC_{CO_2}}{dt} = 6 * k_5 C_{BQ} \qquad (15)$$

554

555

556   For V/N-TiO$_2$ photocatalyst, the mass balance equations are the following:

557 $$\frac{dC_{Bz}}{dt} = -k_1 C_{Bz} - k_2 C_{Bz} \qquad\qquad (16)$$

558

559 $$\frac{dC_{PhOH}}{dt} = k_1 C_{Bz} - k_5 C_{PhOH} - k_7 C_{PhOH} - k_8 C_{PhOH} \qquad (17)$$

560

561 $$\frac{dC_{HQ}}{dt} = -k_3 C_{HQ} + k_2 C_{Bz} + k_7 C_{PhOH} + k'_3 C_{BQ} \qquad (18)$$

562

563 $$\frac{dC_{CT}}{dt} = k_5 C_{PhOH} - k_6 C_{CT} \qquad\qquad (19)$$

564

565 $$\frac{dC_{BQ}}{dt} = k_3 C_{HQ} - k_4 C_{BQ} - k'_3 C_{Bz} + k_8 C_{PhOH} \qquad (20)$$

566

567 $$\frac{dC_{CO_2}}{dt} = 6 * k_4 C_{BQ} + 6 * k_6 C_{CT} \qquad\qquad (21)$$

568

569

570 The differential equations for each photocatalyst are solved considering the initial condition:

571 t=0 $\qquad\qquad$ $C_{Bz} = C_{BZ_0}$

572 t=0 $\qquad\qquad$ $C_{phOH} = C_{HQ} = C_{BQ} = C_{CT} = C_{CO2} = 0$

573

574 The system of differential equations was solved by a numerical procedure using the Euler method.

575 It is the most basic explicit method for the numerical integration of ordinary differential equations

576 (ODEs) with a given initial value. The values of the apparent kinetic constant for each reaction were

577 attained by using the least-squares approach, minimizing the sum of squared residuals between the

578 experimental data acquired at different irradiation times and the values provided by the model. The

579 comparison between the model and experimental results is reported in Figure 12.

580
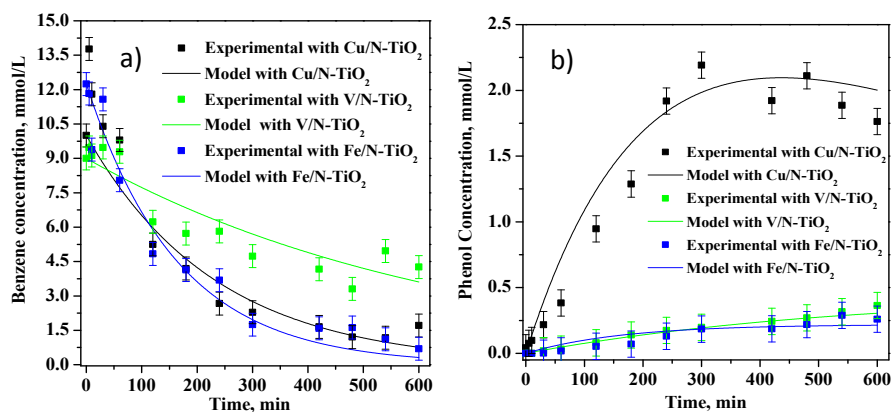

Figure 12. Comparison between model calculation and experimental data to find the model oxidation constant k for benzene concentration (mmol/L) (a); phenol concentration (mmol/L) as a function of time obtained with Cu/N-TiO$_2$, Fe/N-TiO$_2$ and V/N-TiO$_2$ under visible light (b).

Table 5 shows the kinetic constants for phenol production (k$_1$).

Table 5. Phenol production kinetic constants (k$_1$) derived from the proposed mechanism for photocatalytic hydroxylation of benzene considering Cu/N-TiO$_2$, Fe/N-TiO$_2$ and V/N-TiO$_2$ samples.

Photocatalyst	k$_1$ (min^{-1})
Cu/N-TiO$_2$	$1.41 \cdot 10^{-3}$
Fe/N-TiO$_2$	$1.09 \cdot 10^{-4}$
V/N-TiO$_2$	$9.21 \cdot 10^{-5}$

The values of the phenol production kinetic constants evidenced that the Cu/N-TiO$_2$ photocatalyst

showed the highest rate of phenol formation with respect to the other formulated photocatalysts.

Ultimately, Cu/N-TiO$_2$ photocatalyst is more effective as it produces phenol faster than the other

formulated photocatalysts and it allows achieving the highest phenol yield (19%) and selectivity to

phenol (23%) after 600 min of visible light irradiation.

Considering the mechanisms reported in the available literature [53, 64-66], it is possible to argue that

the oxidation of benzene to phenol on Cu/N-TiO$_2$ may occur through the following reactions:

601 $N\text{-}TiO_2 + h\nu \longrightarrow e_{CB}^- + h^+$ (22)

602

603 $Cu^{2+} + e_{CB}^- \longrightarrow Cu^+$ (23)

604

605 $Cu^+ + H_2O_2 \longrightarrow Cu^{2+} + \bullet OH + OH^-$ (24)

606

607 (25)

608

 (26)
609
610
611
612 (27)
613
614
615

616 The hole-electron pairs are produced from the activation of the transition metal oxides or N-TiO$_2$

617 (Eq. 22) under irradiation. Cupric ions could react with the photogenerated electrons, producing

618 cuprous ions (Eq. 23). Therefore, Cu$^+$ ions could be re-oxidized to Cu^{2+} by H$_2$O$_2$, generating $\bullet$OH

619 (Eq. 24). The hydroxyl radical reacts with benzene to generate hydroxylated benzene radical (Eq.

620 25), which is then oxidized by a positive hole (Eq. 25) or by Cu^{2+} (Eq. 26) on the photocatalyst

621 surface and deprotonated, eventually producing phenol.

622

623 **4. Conclusions**

624 Transition metal oxides supported on N-TiO$_2$ (Cu/N-TiO$_2$, Fe/N-TiO$_2$, and V/N-TiO$_2$) were

625 synthesized by incipient wet impregnation and their physico-chemical properties were studied by

626 means of different characterization techniques. Wide-angle X-ray diffraction patterns and Raman

627 spectra showed the presence of signals typical of the anatase crystalline phase for all of the

628   synthesized samples. In the diffraction pattern of Cu/N-TiO$_2$ additional peak related to CuO phase

629   was observed. Additionally, from Raman analysis of V/N-TiO$_2$ sample, bands assigned to the

630   presence of polyvanadates dispersed on the surface were detected. Fluorescence spectra indicated

631   an efficient suppression of the charge recombination for all of the mixed oxide catalytic systems.

632   However, UV-vis spectra evidenced significant electronic interactions between N-TiO$_2$ and the

633   copper oxide, resulting in a remarkable red shift of the absorption edge for the Cu/N-TiO$_2$ with

634   respect to the Fe/N-TiO$_2$, and V/N-TiO$_2$ samples. The obtained mixed oxide photocatalytic systems

635   were employed for the benzene to phenol conversion reaction in presence of H$_2$O$_2$ and under visible

636   light. N-TiO$_2$ showed high benzene conversion (62%) without phenol formation under visible light.

637   A maximum yield towards phenol of ca. 25% was achieved in the presence of Cu/N-TiO$_2$,

638   significantly higher than that observed with Fe/N-TiO$_2$ (2%) and V/N-TiO$_2$ (2.5%). Cu/N-TiO$_2$

639   photocatalyst is more effective as it produces phenol faster than the other formulated photocatalysts

640   and it allows achieving phenol in a selective way (after 600 min, selectivity of 23% with high

641   benzene conversion of 82%). The superior performance of the Cu/N-TiO$_2$ sample can be ascribed

642   partially to the better optical absorption but especially to the low affinity of phenol with the copper

643   oxide component. Indeed, the photocatalytic degradation of phenol was the slowest in the presence

644   of Cu/N-TiO$_2$ photocatalyst, which, on the other hand, showed the highest performance in the

645   hydroxylation of benzene to phenol compared to Fe/N-TiO$_2$ and V/N-TiO$_2$. Finally, Cu/N-TiO$_2$

646   proved to be a very stable catalytic material as any significant decrease both in the conversion of

647   benzene and in the phenol yield after four cycles of reuse was evidenced. Based on the results

648   achieved in this work, for the possible industrialization of a catalytic reactor devoted to the

649   hydroxylation of benzene to phenol in the liquid phase, it is necessary to develop a fixed-bed

650 photoreactor in which a structured catalyst, realized through the immobilization of Cu/N-TiO$_2$

651 photocatalyst on a macroscopic support, is placed. This could prevent a further separation step of

652 the catalytic powders from the liquid medium at the end of the oxidation phase. Moreover, it could

653 be affordable to design efficient and low-cost systems for separating and recovering phenol from

654 the liquid phase, as reported for similar partial oxidation reactions[67].
