PROCEEDINGS

of the American Academy of Forensic Sciences 67th Annual Scientific Meeting

The Proceedings of the American Academy of Forensic Sciences is an official publication of the American Academy of Forensic Sciences (AAFS). It is devoted to the publication of the abstracts of technical oral papers and posters presented at the AAFS annual scientific meeting. These include various branches of the forensic sciences such as pathology, toxicology, anthropology, psychiatry, immunology, odontology, jurisprudence, criminalistics, questioned documents, digital evidence, and engineering. Similar submissions dealing with forensic oriented aspects of the social sciences are also included.

Please note that some of the abstracts included in the Proceedings deal with topics, results, and/or conclusions which are controversial. The publication of abstracts does not imply that the AAFS, its sections, or the individual section program chairs/committee members have verified or agree with the studies, results, and/or conclusions of each abstract. During the process of planning a scientific program, it is impossible to “peer-review” each abstract and presentation to the degree that is accomplished during manuscript review. Abstracts and presentations are accepted, in part, so that they can be critiqued and reviewed by other scientists. Thus, a forum is created to discuss controversial issues.

The views expressed in this publication are not those of the AAFS. The data and opinions appearing in the published material were prepared by and are the responsibility of the contributor(s), not of AAFS nor its respective employees, employers, officers, and agents. The AAFS does not supply copies of meeting papers. Please write directly to individual authors to obtain copies of specific papers. Presentation of some abstracts may have been scheduled or canceled after the publication of this document.

English is the official language of the AAFS and its meetings; neither oral nor written translations will be provided.

S1 Past Presidents Future Science: Hot Leads in Contemporary Forensic Research

*Daniel A. Martell, PhD**, Park Dietz & Associates, 2906 Lafayette, Newport Beach, CA 92663; *Robert E. Barsley, DDS, JD**, LSU School of Dentistry, Oral Health Resources, Rm 5345, 1100 Florida Avenue, New Orleans, LA 70119; *Thomas L. Bohan, PhD, JD**, MTC Forensics, 54 Pleasant Avenue, Peaks Island, MD 04108; *Edmund R. Donoghue, MD**, Georgia Bureau of Investigation, 925 A Mohawk Street, Savannah, GA 31419-1796; *Zeno J. Gerads, PhD**, Netherlands Forensic Institute, Ministry of Justice, Laan van Ypenburg 6, Den Haag, SH 2497 GB, NETHERLANDS; *John E. Gerns, MFS**, Quellenstrasse 17, Enkenbach-Alsenborn, Rheinland Pfalz 67677, GERMANY; *Carol Henderson, JD**, Stetson University, College of Law, 1401 61st Street, S, Gulfport, FL 33707; *Barry K. Logan, PhD**, NMS Labs/CFSRE, 3701 Welsh Road, Willow Grove, PA 19090; *Richard Rosner, MD**, 140 E 83rd Street, Ste 6A, New York, NY 10028; *John L. Sang, MS**, 1 Harbor Lane, Glen Head, NY 11545; *Ronald L. Singer, MS**, Tarrant County MEO, 200 Feliks Gwozdz Place, Fort Worth, TX 76104-4919; *Douglas H. Ubelaker, PhD**, Smithsonian Institution, Dept of Anthropology, NMNH, MRC 112, Washington, DC 20560; *Elizabeth A. Murray, PhD*, College of Mount St Joseph, Dept of Biology, 5701 Delhi Road, Cincinnati, OH 45233-1670; and *Jeri D. Roper-Miller, PhD*, RTI International, 3040 Cornwallis Road, PO Box 12194, Bldg 7, Rm 211, Research Triangle Park, NC 27709

After attending this presentation, attendees will: (1) describe many future directions of disciplines within the American Academy of Forensic Sciences; (2) recognize cutting-edge research and technologies in a variety of forensic science fields; (3) predict how law and forensics will be shaped by today's leaders in the coming decade; and, (4) discuss the future of forensic science with those in their own fields as well as other disciplines.

This presentation will impact the forensic science community by assembling visionaries in all 11 sections of the American Academy of Forensic Sciences who will discuss contemporary issues in their respective fields. Speakers will emphasize hot leads from the laboratory, theoretical advances, and emerging technologies.

The Past Presidents of the American Academy of Forensic Sciences (AAFS) represent a vast repository of forensic science knowledge, insight, and wisdom. As a group, they are unique in the world with regard to the scope of their collective influence and leadership vision in the forensic sciences. This year's Interdisciplinary Symposium will harness the energy from this eminent group of forensic scientists and focus it on the Academy's future. The Interdisciplinary Symposium will showcase Past Presidents and other representatives from each of the Academy's 11 sections. The speakers will share their vision for the future of forensic science in their respective disciplines, emphasizing hot leads from the laboratory, theoretical advances, and emerging technologies. The goal of this program is to envision where the forensic sciences will be a decade from now, the impact of these emerging advances on the law, and our place in it. This historic endeavor will be of significant interest to all Academy members and will provide a unique forum for learning from each other about the future of forensic science. Current AAFS President, Daniel A. Martell, PhD, will provide the Interdisciplinary Symposium's introductory remarks.

Anthropology

Douglas H. Ubelaker, PhD — AAFS Past President (2011-12): Dr. Ubelaker believes that predicting the future of any discipline can prove challenging, yet current trends and developments provide useful clues. Within forensic anthropology, Dr. Ubelaker sees these trends related to issues of certification, accreditation, the nature of case applications, employment, training, enhanced methodology, and new research.

Criminalistics

Ronald L. Singer, MS — AAFS Past President (2004-05): Mr. Singer says there is a familiar quote with regard to this topic: "May you live in interesting times." According to Mr. Singer, the future of criminalistics is indeed going to be interesting. Technological advances and the increased reliance on computer-driven systems and databases will reduce the time required for analytical processes, will make them more specific, and even allow many procedures to be handled at the crime scene as opposed to the laboratory. Using advanced DNA technologies, we will be able to predict physical features of unknown donors; probative information will be obtained from smaller and smaller samples; computer-assisted evaluation of the surfaces of fired bullets and cartridge cases will reduce the subjectivity involved in those analyses; and database searches will become faster and more accurate. With these advances come many challenges that will also have to be addressed. In some instances, criminalists will have to shift their focus from the bench to the preparation and monitoring of protocols for methods actually applied by non-scientists. In the laboratory, quality and accountability to our clients, the public, and the judiciary will continue to dominate our processes, but with considerably more oversight from outside

Special Session - 2015

bodies. This will inevitably impact our ability to deliver the services expected of us. As mandatory certification and accreditation become realities, education and training demands will increase, creating financial and staffing burdens on agencies, which in many cases will be met by a regionalization of some services, and an increased cooperation between laboratories. The Past Presidents from the Criminalistics Section are confident that these changes will lead to a vibrant future for the discipline.

Digital & Multimedia Sciences

Zeno J. Geradts, PhD — AAFS Director (2010-13): The Academy's newest section, Digital & Multimedia Sciences, is represented by Zeno J. Geradts, PhD. With regard to future expectations, Dr. Geradts, in conjunction with his section's working group, expects developments in big data analytics as well as multimedia analytics, due to the exponentially growing size of data. The use of strong encryption in data sources as well as communication channels is expected to rise. For that reason, forensic investigation of cloud computing, local storage media, silicon chip forensics, and mobile forensics will remain important. It is expected that many devices will be increasingly connected to the internet, such as robotic vacuum cleaners, other household appliances, as well as various medical devices; this is being increasingly described as the "internet of things." Forensic analysis of log files and location data of these and other tools will be more important in relation to crime scene investigation.

Engineering Sciences

Thomas L. Bohan, PhD, JD — AAFS Past President (2009-10): Having presided during the first year following the release of the 2009 National Academy of Sciences Report, *Strengthening Forensic Science in the United States: A Path Forward*, part of his presentation will deal with the effect — or to date — the "non-effect" of that report on forensic engineering sciences. Engineering science practitioners come from a diversity of disciplines practically as wide as that of the AAFS itself. They include "rocket scientists" (really, engineers), space physicists, medical device designers, transportation experts, materials testers and developers, fire investigators, and nearly everything except practicing physicians and attorneys, though some engineering scientists are physicians and attorneys as well. As such, they will be intimately involved in the complex activities shaping our society in the near and, it is hoped, distant future. It will be, to an even greater extent than at present, an electronically monitored society. This monitoring includes governmental surveillance and automotive "black boxes," but also includes the microprocessor-coupled systems that "observe" and control our airplanes, ventilation systems, and surgical procedures. This monitoring is data-based and it produces data; however, it occasionally fails in its assigned control tasks. Planes crash, surgical suites catch on fire, and building designs incorporate dangerous flaws. In the recipe for resolving the civil and criminal disputes created by such failures, practitioners from the forensic engineering sciences comprise the most common ingredient, often exceeding in number even the litigators. Dr. Bohan's presentation will explore this role of his colleagues and how it will be affected by forensic reform measures when they are finally applied to the forensic engineering sciences.

General

John E. Gerns, MFS — AAFS Secretary (2013-15): Diversity of the General Section will continue to play a pivotal role in the future horizons of the forensic sciences. In keeping up with the changes being driven by the National Institute of Science and Technology (NIST) Organization for Scientific Areas Committees (OSAC) and Congressional Legislative action, the General Section's Ad hoc Long Term Planning Committee is developing a long-term strategic plan which will serve as the General Section's "blueprint for our future." This is critical since many of our forensic disciplines fall under several of these new guidance committees. Discussion will focus on the potential challenges that face several of our forensic disciplines in the future, along with innovations in those disciplines which will enhance the application of the forensic sciences to the investigative mission.

Jurisprudence

Carol E. Henderson, JD — AAFS Past President (2008-09): Law and science have long been engaged in what has been called a reluctant embrace. The vast majority of civil and criminal cases involve scientific evidence that requires forensic scientists to comply with certain admissibility rules. While the legal system has usually reacted to emerging scientific discoveries, more recently it has been proactively striving to formulate a more robust legal/scientific framework for the introduction of scientific evidence into the courtroom. Topics to be explored in this presentation include trends regarding the admissibility of forensic evidence, the role of national and international organizations in shaping policies and guidelines to strengthen the foundation and acceptance of forensic science, strides made toward requiring more rigor in methodology of various fields of forensic science, judicial recognition of accreditation and certification, and current efforts to ensure lawyers and judges have the expertise necessary to comprehend and evaluate forensic evidence.

Odontology

Special Session - 2015

Robert E. Barsley, DDS, JD — AAFS Past President (2012-13): The future for the Odontology Section will include progress in four key areas in the field. First, in the identification of unknown human remains, the digitization and adoption of the electronic health record on a worldwide scale will greatly improve the capture and transferability of the biometric data underlying dental identification. In particular, the rapid adoption of digital radiographic imaging not only benefits traditional methods of dental comparison but has also impacted the second area undergoing rapid development — dental aging. This includes age at time of death for unidentified remains as well as the use of oral-facial development to determine the age of living individuals, a technique important in immigration status, employment status, and even in criminal matters in various jurisdictions. The adoption of digital imaging has also played a key role in renewed interest in dental markers for sexual dimorphism. The third field is the study of dental biometric analysis in disaster victim identification. The “richness” or “granularity” (the detail) of dental data captured and then used in the calculations that develop and rank-order antemortem and postmortem findings is an area enjoying rapid development. At the same time, odontologists are working across disciplines to develop unified identification software that allows those disciplines to share and use information as needed to complete identifications. Finally, the area of dental-related patterned injury (bitemark) analysis is under intense scrutiny. In addition to at least one recently completed National Institute of Justice (NIJ) -funded study, numerous ongoing and completed studies are focused on pattern comparison, tissue injury and response in living test subjects, and the area of cognitive bias. A project to provide a decision tree for analysis and comparison of human bitemarks that may be useful in suspected biter linking and/or exclusion is underway as well.

Pathology/Biology

Edmund R. Donoghue, MD — AAFS Past President (2005-06): Dr. Donoghue reports that, at present, the future of forensic pathology appears good. Easy gains can be accomplished by distributing currently existing radiology and computer-imaging technology to medical examiner offices. A number of situations could create difficulty for forensic pathology in the future. If the American Board of Pathology drops its current requirement for forensic pathology training, hospital residents would no longer join medical examiner offices and could not be recruited for training in forensic pathology. Maintenance of certification and re-certification examination requirements are burdensome and create the possibility that some forensic pathologists might become unemployed in the future. Standards for accreditation of medical examiner offices and autopsy standards are becoming increasingly detailed and rigorous. These standards may be obtainable with adequate staffing, infrastructure, and funding, but may become unreachable when resources are scarce. Forensic pathologists will need to be vigilant to avoid over-regulation by the federal government and other entities.

Psychiatry & Behavioral Science

Richard Rosner, MD — AAFS Past President (1996-97): Dr. Rosner states, “As one wit put it, ‘Prediction is always difficult, especially about the future.’” Given that caveat, the foreseeable future of forensic psychiatry and behavioral science will have at least two facets. On the one hand, the current effort to advance neuroscience (e.g., the United States government’s proposed \$100 million Brain Research Through Advancing Innovative Neurotechnologies (BRAIN) initiative is likely to advance our knowledge of the functioning of the brain and increase the scientific basis for our specialty). On the other hand, as noted by Thomas Nagel in his recent book, *Mind and Cosmos*, certain basic problems are likely to remain either unaddressed or inadequately addressed. These problems include the nature of consciousness, the relationship of the brain to the mind, and whether or not our subjective experience of “free will” is credible. Because our concept of personal responsibility (e.g., for criminal behaviors) is inextricably linked to those three issues, the impact of the anticipated scientific advances will be limited.

Questioned Documents

John L. Sang, MS — AAFS Past Vice President (2010-11): The future of questioned documents will likely be inclined toward digital signature examination and the use of automatic forensic handwriting analysis systems by Forensic Document Examiners (FDEs) to assist in case work. Certainly, handwriting examinations will become more data oriented and the field will see more measurement data and statistical analyses being conducted. Eventually, the field may get to the point where a machine can conduct a full examination, comparison, and analysis of handwriting; however, this is still a very long way down the road. In any event, a human examiner will still have to make the final decision. Clearly, the numbers of FDEs are declining and there will be very few government positions or a cadre of highly-skilled private FDEs as in Osborn’s days. There are a good number of jurisdictions that can’t afford to have FDEs, including state, local, and law enforcement agencies. The field is barraged with an influx of individuals, generally graphologists, who claim to have been trained as FDEs via internet instruction and training. These people do not come close to meeting the minimum standards required by the AAFS Questioned Documents Section; however, they are often allowed to testify as experts. Hopefully, the courts will stem this problem but, for now, that seems unlikely. It would make sense that the courts require FDEs to be certified before they can testify. The Questioned Documents Section has worked hard over the years to have a strong certification program through the American Board of Forensic Document Examiners (ABFDE) and a good network of professional organizations. A good base of standards has been developed by the American Society for Testing and Materials (ASTM)/the Scientific Working Group for Forensic Document Examination

Special Session - 2015

(SWGDOC). The new National Institute of Standards and Technology (NIST) and its Law Enforcement Standards Office (OLES) will be discussed in the presentation. A high priority will be the continuing research into Terminology for Expressing Conclusions of FDEs, and it is expected that all standards will grow stronger every year moving forward. Improvements in printing technology and 3D printers will provide more challenges and opportunities for FDEs. More research will be conducted into data produced by devices used to create mechanically produced signatures. Development of different types of toners and inks will also provide more challenges. For years, Mr. Sang has believed the field will be moving closer to the digital sciences. He hopes the courts will clearly see what a significant and progressive field forensic document examination is as practiced by our members at the AAFS.

Toxicology

Barry K. Logan, PhD — AAFS Past President (2013-14): Forensic toxicology is undergoing a change of focus and direction as we convene in Orlando in 2015. The focus for the last two decades has been on pushing the limits of laboratory technology to tweak the sensitivity of Gas Chromatography/Mass Spectrometry (GC/MS) methods, the workhorse instrument in the laboratory, to the point where we have techniques with adequate sensitivity to answer most questions about whether a person ingested or was exposed to forensically significant amounts of commonly encountered toxic or intoxicating substances. Going forward, the focus is on the next generation of Liquid Chromatography/Mass Spectrometry (LC/MS) instrumentation with less demanding sample preparation requirements to achieve faster throughput and to help identify some of the more esoteric compounds and their metabolites not amenable to GC/MS analysis. Identifying the optimum techniques from Time-of-Flight (TOF) to MSⁿ and beyond in their various combinations and finding economical ways to sort and evaluate the data will be a focus in the immediate future. The second main area of change is in standards development. The Scientific Working Group for Toxicology (SWGTOX), a collaborative consensus-building approach to standards development, has achieved an incredible amount in the five years it has been in existence, and is challenging forensic toxicology labs and practitioners to refine and validate their methods and to ask more of the labs in improving quality and in estimating error and uncertainty in quantitative measurement. As SWGTOX transitions to a subcommittee of the Forensic Science Standards Board (FSSB), it has produced a solid legacy on which to build a strong future. Combined, these two major initiatives will force a harder focus on what the results mean and what they tell us about the likelihood of an adverse effect or life-threatening condition. Drug interactions, pharmacogenomic differences in drug metabolism, the influence of tolerance in interpretation, and other factors will all have to be addressed in a more systematic way in interpretive toxicology. The Toxicology Section of the AAFS is working to equip today's and tomorrow's forensic toxicologists to answer these questions.

The AAFS Interdisciplinary Symposium for 2015 will be one of the highlights of the Academy meetings in Orlando. Attendees will hear from preeminent visionaries in their respective fields. The collection of speakers, the great majority of whom are Past Presidents of the American Academy of Forensic Sciences, represent a diverse and interdisciplinary view of the direction forensics will take in the years to come. These experts are not only familiar with the past in their fields, but are also looking forward to the future.

Future of Forensic Science, Past Presidents of AAFS, Contemporary Research

S2 YFSF 20th Anniversary: The Past, the Present, and Our Future

Lara Frame-Newell, MA, 400 E Jackson Street, Richmond, VA 23219; Christina G. Hayes, BS, 1200 Clark Avenue, St. Louis, MO 63103; Jessica Smith, 2820 El Lago N Drive, Apt A, Indianapolis, IN 46227; Katherine E. Maciag, BS, 14502 Polo Club Drive, Strongsville, OH 44136; Betzaida L. Maldonado, BS, 1357 Park Street, Apt 3, Huntington, WV 25701; Lindsay Saylor, 6258 W 60th Street, Chicago, IL 60638; Kate M. Lesciotto, JD, 117 Moorehead Street, Erie, PA 16508; Jennifer Curnow, MS, 15 Chichester Drive, Apt 304, Stafford, VA 22554; Melanie E. Boeyer, BS, 5044 E Oak Ridge Circle, Erie, PA 16509; Alicja K. Lanfear, PhD, Middle Tennessee State University, Department of Biology, Box 60, Murfreesboro, TN 37132; Tiffany B. Saul, MS, 9919 Thunderbolt Way, Knoxville, TN 37923; Sarah J. Ellis, MS, North Carolina State Crime Laboratory, 121 E Tryon Road, Raleigh, NC 27603; Brianna B. Bermudez, 9112 Surrey Road, NE, Albuquerque, NM 87109; Daniel A. Martell, PhD*, Park Dietz & Associates, 2906 Lafayette, Newport Beach, CA 92663; Victor W. Weedn, MD, JD*, George Washington University, 2100 Foxhall Road, NW, Somers Hall, Lower Level, L-12, Washington, DC 20007; Cheryl D. Hunter*, 403 Pioneer Creek Drive, Florissant, CO 80816; Jane A. Lewis, MFS*, 544 E Ogden Avenue, Ste 700-289, Milwaukee, WI 53202; John P. Kenney, DDS, MS*, 101 S Washington Street, Park Ridge, IL 60068-4290; Ruth E. Winecker, PhD*, OCME, 3025 Mail Service Center, Raleigh, NC 27699-3025; Elizabeth Richards, PhD*, Defense Forensic Science Center, 4930 N 31st Street, Bldg 925, Forest Park, GA 30297; Anjali A. Ranadive, JD*, SciLawForensics, Ltd, 1834 Overlook Ridge Road, Brookings, SD 57006; Christine Funk, JD*, Department of Forensic Sciences, 401 E Street, SW, Washington, DC 20024; Mark Pollitt, PhD*, Digital Evidence Professional Services, Inc, 8509 Nicole Court, Ellicott City, MD 21043; Ken Williams, MS, JD*, New Jersey State Police, North Regional Laboratory, 1755 State Highway 46, Little Falls, NJ 07424; John Nixon, MBA*, ARC, PO Box 66, Bippus, IN 46713; Nicolene Lottering, BS*, Queensland University of Technology, School of Biomed Sci, Faculty of Health, 2 George Street, Gardens Point, Brisbane, Queensland 4001, AUSTRALIA; Diane B. Fraser, MSFS*, 411 Eastview Drive, Fort Walton Beach, FL 32547; Ann H. Ross, PhD*, North Carolina State University, Sociology & Anthropology, Campus Box 8107, Raleigh, NC 27695-8107; and Barry A.J. Fisher, MS, MBA*, 81620 Avenida Estuco, Indio, CA 92203

After attending this presentation, attendees will have a better understanding of future trends in forensic science. In addition, attendees will learn about casework and research that has been done by their peers at Bring Your Own Poster (BYOP) and Bring Your Own Slides (BYOS) Sessions. Networking skills, how to succeed in the current job market, and career preparation will also be discussed.

This presentation will impact the forensic science community by demonstrating future trends in forensic science through casework, education, and mentorship opportunities as well as by providing tools for successful contributions to the forensic science field.

Each year at the American Academy of Forensic Sciences (AAFS) Annual Scientific Meeting, the Young Forensic Scientists Forum (YFSF) provides a program for a group of students and forensic scientists with less than five years of professional experience. The session allows participants to interact with their peers as well as with the professional speakers and to build professional relationships that foster growth and mentorship opportunities. Special session topics provide attendees with a broad overview of the many opportunities in the field of forensic science. In addition to the special session, YFSF offers two opportunities for young forensic scientists to present their own work or research: the YFSF Bring Your Own Posters (BYOP) Session and the YFSF Bring Your Own Slides (BYOS) Session. The Forensic Sciences Foundation (FSF) Emerging Forensic Scientist Award winner is also invited to present her award-winning paper during this special session.

For the AAFS 67th Annual Scientific Meeting in Orlando, FL, the YFSF Special Session will present *YFSF 20th Anniversary: The Past, the Present, and Our Future*. The special session includes speakers from many of the AAFS sections who will discuss personal experiences and improvements within the field of forensic science. Through the presentation, attendees will learn how various forensic fields are changing and what opportunities are available to undergraduate students, graduate students, and young professionals. Speakers will discuss educational and professional requirements in their respective fields as well as skills needed throughout the forensic science community.

Following the Tuesday session, the YFSF BYOP Session will be presented in the evening, giving young professionals the opportunity to showcase current cases and research in a poster format.

The annual YFSF BYOS Session takes place the evening of Wednesday, February 18, and will include presentations from students and new forensic scientists. The program will conclude Thursday, February 19, 2015, with the annual YFSF Breakfast Session which includes a resume review panel.

Special Session - 2015

As in past years, the Breakfast Session will maintain focus on developing professional skills for the next generation of forensic professionals. Representatives from educational institutions, professional organizations, and various careers will present on career skills including networking and career preparation. The topics discussed will assist emerging scientists as they determine what careers they would like to have. After the presentations, attendees will have the opportunity to receive résumé assistance and feedback from AAFS members already established in their careers.

The Special Session provides students, young professionals, and AAFS members with a way to foster career-long relationships. The main goal of the YFSF is to encourage mentorship between young and veteran forensic scientists. Participants are encouraged to apply for membership in the AAFS and are given guidance on the many opportunities available to aid in career enrichment.

YFSF, Education, Research

Breakfast Seminar - 2015

BS1 Wildland Fires of Electrical Origin — Deaths and Litigation

Helmut G. Brosz, PEng, BASc, Brosz Forensic Services, 64 Bullock Drive, Markham, ON L3P 3P2, CANADA*

After attending this presentation, attendees will better understand some of the causes of wildland fires resulting in deaths, injury, and litigation, resulting in a more effective understanding of forensic methods and issues.

This presentation will impact the forensic science community by providing information to the legal, insurance, electrical utility, and forensic engineering industry as well as authorities having jurisdiction that become involved in wildfire losses, claims, litigation, and investigation. At the outset, the cause of a wildfire is often not known. Investigation after the “smoke” has cleared requires specialized knowledge and methodology in order to determine the origin, cause, and reason for the initiation of a wildfire. Spoliation issues will also be discussed.

California, Australia, and Florida share a high number of wildfires caused by or involving power lines, lightning, animals, carelessness, vehicles, arson, etc., and other unusual causes. Wildfires have caused thousands of deaths (directly and indirectly), property destruction of dwellings and infrastructure, and business interruption. The millions of dollars of loss invariably result in civil litigation if a chance of monetary recovery is likely. Criminal litigation is also likely if the proper circumstances exist.

Issues such as sag and tension of power lines before and after a fire and line-to-line and line-to-ground voltages need to be considered. Clearances from vegetation (trees) and clearances to ground at various temperatures often require not only measurements but catenary calculations and elongation characteristics of copper, aluminum, and Aluminum-Conductor Steel-Reinforced (ACSR) wires. Sometimes energized power lines sag into vegetation due to the heat from a fire below and then make contact with vegetation. The track left by the arcing event may sometimes be interpreted as causal as opposed to resulting.

The importance of accurate surveys of sections of overhead distribution lines along with the ground below are often necessary to determine if the overhead line was built according to applicable codes and standards.

Animals and birds sometimes cause short circuits on lines and at hardware on poles. Animals may fall to the ground while on fire and initiate a wildfire at the base of the pole, giving the appearance of the fire having been caused by utility apparatus. The origin will be at a pole, the cause will be the bird/animal, but the reason will be known only to this critter. Responsibility is sometimes focused on the electric utility and not on the animal. Laboratory simulation tests in a high-voltage lab as well as field tests with portable equipment can be of assistance at these times. Lightning discharges on electrical lines, poles, and hardware can also start wildfires.

The Topanga Canyon wildfire of 1993 near Malibu, Los Angeles County, CA, burned 19,000 acres at a high speed in a span of a few hours; burned 739 structures, homes, and cars; killed three people; and, provides an example of a criminal arson investigation gone awry.

The Cavendale fire of 1996 burnt about 3,000 acres of mostly vineyards in Sonoma and Napa Valley, CA, as well as a few structures. Did a tree grow into a line or did a line sag into a tree? Did a Steller’s Jay bird commit animal electrical suicide? Did California wines develop a smoky taste that year? More than \$30,000,000 was at stake in the ensuing litigation.

Wildfires are here to stay and death, destruction, litigation, and the rebirth of forests and fields continues.

Wildfire, Electrical, Litigation

Breakfast Seminar - 2015

BS2 Mental Health Support to Law Enforcement: Practical Issues

*R. Gregg Dwyer, MD, EdD**, Medical University of South Carolina, Community & Public Safety Psychiatry Division, 29-C Leinbach Drive, Charleston, SC 29407; *Eric Skidmore**, South Carolina Law Enforcement Assistance Program, 2501 Heyward Street, Columbia, SC 29205; and *Andy Gruler, MSW**, 12 Crosswinds Way, Greer, SC 29650

The goal of this presentation is to provide a description of mental health services for law enforcement personnel with guidance on the establishment and maintenance of such services.

This presentation will impact the forensic science community by providing guidance on developing and implementing a mental health program for personnel exposed to exceptionally stressful work environments and content.

Although police work has always had the risk of negatively impacting the mental health of line law enforcement forensic personnel through their exposure to violent crime scenes, officer-involved shootings, line-of-duty deaths, and other critical events, services have been limited. There are multiple combinations and settings in which mental health services can be provided to the law enforcement community. They vary from answering informal questions to formal consulting contracts for service with the mental health professional embedded in an agency for real-time access by law enforcement personnel. Services include pre-employment screening, fitness-for-duty evaluations, training on stress prevention and management, post-critical incident services, responding real-time to crime scenes, Special Weapons and Tactics (SWAT) operations, hostage and barricaded person negotiations, threatened suicide-in-progress, officer-involved shootings, and other traumas. This seminar provides an overview of the types of services available, the necessary and suggested credentials to be an effective consultant, a how-to guide for finding and recruiting such a consultant, and potential conflicts with dual-agency relationships, all presented using actual examples from the field.

Stress Management, Mental Health, Critical Incidents

Breakfast Seminar - 2015

BS3 Bank Robbery on Chicago's South Side — 75 Years After John Dillinger

Brian S. Clark, MFS, 15321 S 94th Avenue, Orland Park, IL 60642*

The goal of this presentation is to introduce attendees to the current difficulties and challenges of investigating violent crime from both an investigator's and a forensic science perspective.

This presentation will impact the forensic science community by creating a better understanding of the crime of bank robbery and the evidentiary issues associated with the crime.

The crime of bank robbery has been the subject of many Hollywood movies, books, and news stories in the United States since the mid-1800s. These events have sometimes been portrayed as glamorous and at other times as the violent and desperate actions of someone with nothing to lose. The closure rate on bank robbery cases varies over time based on numerous variables such as the skill and experience of the robber, the statement of the victims and witnesses, and the location of responding local police officers. However, the quality and amount of evidence available to investigators continues to climb.

As various examination methods of biological evidence get more sensitive, training is provided to bank employees on the importance of preparing the bank counters and other surfaces for the day. It is incumbent on the bank employees to ensure surfaces used by customers and potential bank robbers are cleaned each and every day to help ensure that the biological material from previous customers and employees is removed prior to a robbery.

This presentation consists of a review of several bank robberies on the south side of Chicago to include unarmed note jobs to high-profile takeover-style robberies with multiple subjects with an emphasis on the forensic evidence used in the investigation or lack thereof. Included is the unique experience of an investigating agent on bank robbery investigations who also undertook the responsibility on several occasions to process the evidence involved with the crime scene, the subsequent arrests, and any related search warrants.

Three cases will be presented that illustrate the difficulties and challenges of investigating the crime of bank robbery. The first case is a copy of the movie, *The Town*, in which the robbers, a man and a woman, dressed as nuns, robbed the bank at gunpoint. The second case is a robbery in which the robber conducted reconnaissance from inside the bank as well as surveillance of the bank prior to the robbery. The subject attempted to use the Crime Scene Investigation (CSI) effect leading up to trial and during sentencing to argue that absence of evidence is, in fact, evidence of absence proving that he was kidnapped and placed under duress which resulted in him robbing the bank. A range of video, forensic, digital, and circumstantial evidence was used to convict the subject. The third case involved two individuals who traveled to the Chicago area to rob a bank and planned to flee back to Oklahoma. After preparing for the robbery by obtaining disguises, a rental vehicle, weapons, and a scanner, they robbed a bank, only to be followed by a local tow truck driver who called the police, directing responding officers to the getaway vehicle. The chase was recorded by police dashboard cameras while one of the subjects called 911 to demand they be allowed to escape, ultimately threatening and firing a bullet into another vehicle before crashing into a police car.

Bank Robbery, Chicago, FBI

BS4 Crime Scene Reconstruction of Nine United States Air Force Members Killed in Kabul, Afghanistan

Chad W. Hutchins, MFS, 652 Mossy Oak Trail, Waverly, GA 31565; and Alison R. Babcock, MFS, 1030 S Aspen Street, Buckley AFB, CO 80011*

After attending this presentation, attendees will understand some principles of crime scene reconstruction, such as how to gain explicit knowledge from a series of events or event segments that surround the commission of a crime, the application of deductive and inductive reasoning, the integration and interpretation of physical evidence, strict adherence to the scientific method, and the interrelationship of all the components into a final product.

This presentation will impact the forensic science community by demonstrating how crime scene reconstruction can enhance an investigation with critical interdisciplinary reliance. Crime scene processing techniques, criminalistics, digital sciences, pathology, serology/toxicology, firearms analysis, and other disciplines of forensic science all contribute vital information in this example of a practical application of crime scene reconstruction.

On April 27, 2011, eight United States Air Force (USAF) active duty members and one civilian were murdered by a trusted Afghan pilot being mentored by the USAF members in a surprising blitz-style attack. The incident took place in the two-story Afghan Air Corps Headquarters building on the Afghan Air Force's side of the Kabul International Airport, Kabul, Afghanistan. Just before a routine weekly meeting, seven USAF active duty members and one civilian were gunned down in the Afghan Air Command and Control Center (ACCC); the meeting was to take place just minutes later in an adjoining conference room. The eighth USAF active duty member was murdered just outside the building after he and another active duty USAF member exited the conference room and engaged the gunman throughout two separate hallways of the headquarters building. The gunman was wounded at some point during the gun fight, which left clues to his actions before he walked to the second floor of the building where he sustained two fatal gunshot wounds to the chest.

Four different multi-national response and law enforcement teams processed the scene before the Air Force Office of Special Investigations (AFOSI) was allowed unrestricted access five days later. By this time, furniture had been moved from its original position and cleaned, all visible projectiles and cartridge casings had been collected in a manner which made it impossible to determine exactly where they had come from, blood on the floors and walls had been cleaned and painted over, glass containing bullet holes had been replaced, and the decedent's clothes had been incinerated.

Many questions were immediately asked. Was there more than one gunman? If not, how could one person murder this many military members, most of whom were armed, without being stopped? Crime scene reconstruction was the only way to take this extremely complex case with fragmented physical evidence from a severely contaminated crime scene and produce answers.

Statements from several Afghan witnesses present in the ACCC were used to aid in the reconstruction; however, available physical evidence and autopsy findings were crucial. The rest of the reconstruction, spanning a building of approximately 14,000 square feet, relied heavily upon interpreting physical evidence, deductive and inductive reasoning, and applying the scientific method to come to conclusions.

Many times a crime scene reconstruction is accomplished to answer a specific question or sequence specific events involved in a crime. In this case, the reconstruction was performed to simply identify the major event segments and place them in as much of a sequence as possible in an effort to answer the question, "What happened?" This enabled the conclusion of only one gunman and provided clues as to how one person could carry out a murder spree against military personnel who were carrying weapons.

Reconstruction, Scientific Method, Afghanistan

BS5 The Roso Case: An Unpublished Trial Regarding Hermaphroditism Verified Through the Expertise and Written Advice of Leading Physicians in 19th-Century Florence

Annarita Franza, PhD, Via delle Oche 15, Florence, Italy, ITALY; and Vincenzo Lusa, JD*, Via Ferdinando, Palasciano #72, Rome 00151, ITALY*

After attending this presentation, attendees will understand the techniques and methods used at what, in 19th-century Europe, was considered a famous trial: the case of Maria Rosa Fantini (1764-1839), which centered on a series of reports regarding the very delicate issue at the center of a case of “doubtful sex” and who was later shown to be a hermaphrodite. This trial remained buried in the Archiepiscopal Archives of Florence and has only recently been brought to light.

This presentation will impact the forensic science community by illustrating the importance of introducing, at trial, the technical expertise and opinions of such famous Italian doctors of the time as Vincenzo Chiarugi (1759-1820), the father of Italian psychiatry. In addition, attendees will better understand how the methods of the Positivist School, which had shaped such forensic scientists as the criminal anthropologist Cesare Lombroso (1835-1909), were able to demonstrate a person’s true sexual identity with psychological developments that emerged in court, thus revolutionizing the perception each individual has of themselves. During the presentation, the previously unpublished court records and reports of this particular case will be presented along with the findings of the proceedings.

The research conducted at the Fiesole (Italy) Diocesan Historical Archives has permitted a reconstruction of Fantini’s life. On July 15, 1805, an initial application was filed at the Court of the Episcopal Curia of Fiesole by the husband, Dionisio, to dissolve his marriage to Maria Rosa, whose poor genital conformation invalidated the marriage. Subsequently, on February 13, 1818, Dionisio, convinced of his marriage’s illegality, brought action for an annulment before the Episcopal Court of Florence where, at the behest of the lawyer Simeone Döthel, a second report, entrusted this time to Vincenzo Chiarugi, was filed. The examination showed a surprisingly large enterocele in the right groin area and, at the uppermost part of the pubic arch, a glans imperforate, resembling a foreskin circumcision, and a very well-built frenulum that forced the glans toward the bottom. On the basis of anatomical data, Chiarugi concluded that Maria Rosa was a male. The clinical history found in the Historical Archives of the University of Florence, shows that Maria Rosa was admitted to the women’s ward, where the anatomist Giuseppe Chiarugi, son of Vincenzo Chiarugi, identified her as being a male. She was then transported to the men’s infirmary (bed number 598) and given the masculinized name of Roso. On her deathbed, she declared her regret that, “In the midst of the confusion of the opposite sex, I am and was a woman and I am surprised at how these gentlemen want me to die here among men.” Maria Rosa died at 11:00 a.m. on the morning of April 16, 1839, in the men’s ward of the Santa Maria Nuova Hospital. The autopsy, performed by Stanislao Petri, confirmed the previous forensic report. As evidenced by copies of the death certificate, found at the Florence State Archives and the Archiepiscopal Historical Archives of Florence, the deceased was recorded under the name of Roso Fantini, an unmarried male.

The case of Maria Rosa “Roso” Fantini provides valuable material for scientific research and an unpublished look at Italian positivism regarding the nascent “sexual question.” The extraordinary nature of this now-forgotten case was mentioned by Caesar Taruffi (1821-1902), Professor of Pathology at the University of Bologna and a leading expert on hermaphroditism in the period in the work *Ermafroditismo ed agenosoma* (1902). In keeping with the dictates of scientific writing at the time, Vincenzo Chiarugi’s forensic report was published in the form of letter (*Sopra una supposta specie di ermafroditismo*, 1819) highlighting indirect evidence of Maria Rosa’s sexual behavior. Having been raised and having lived as a female, she believed that she had been born and lived as a woman. Trials in that period demonstrated that, in instances of “ambiguity,” it was possible to divert “nature” from its course, as in the case of Maria Rosa, psychologically changing a male into a female. On the subject of hermaphroditism, Cesare Lombroso, from the School of Criminal Anthropology, also strongly supported the influential role of education in the formation of sexual identities.

Hermaphroditism, Trials, Case Report

Breakfast Seminar - 2015

BS6 Recent Changes in Pharmaceutical Industry Operations: Boon or Bane?

Abraham T. Philip, MD, Regional MEO, 325 Norfolk Street, Newark, NJ 07103*

WITHDRAWN

BS7 The Businessman, the Wife, the Aunt, and the Children: Multiple Murders by Drowning

Chris Milroy, MD, LLB, Ottawa Hospital, 501 Smyth Road, Box 117, 4th Fl CCW, Ottawa, ON K1H 8L6, CANADA*

After attending this presentation, attendees will understand “honor killings” and the role they play in certain societies, the pathology of drowning, and the importance of a complete death investigation system.

This presentation will impact the forensic science community by providing an understanding of the importance of a full autopsy in drowning cases and the role that cultural values play in supplying a motive for some homicides.

On June 30, 2009, near the City of Kingston, Ontario, a car was found in the Rideau Canal, a 126-mile (202km) canal that runs between Ottawa and Kingston, Ontario. When a diver located the car, there were four bodies present. The bodies were recovered and a Nissan® Sentra® car removed from the water. On the same day, a Canadian businessman of Afghani origin reported that three of his daughters, aged 19, 17, and 13 years of age were missing along with their 50-year-old aunt. The father reported that they had been on holiday at Niagara Falls, were returning to Montreal, and stopped at a motel for the night. The 19-year-old daughter, who had apparently been learning to drive, was reported to have taken the car keys to the Nissan® Sentra® stating she needed something, and had then driven off with her aunt and sisters.

When the bodies were recovered, the police initially assumed the deaths were an accident. Postmortem examinations were conducted and the deaths were recorded as drownings. Toxicological analysis of the four victims was negative.

However, soon after the deaths, Kingston police became concerned that the deaths were not accidental. The oldest son of the businessman had reported that he had been involved in an accident with his car in Montreal on the morning the bodies had been found and had reported the crash to the Montreal police, though no other car was involved. However, glass found at the scene in Kingston indicated that the glass was from the Lexus® (which had a defect in the headlight) the son was driving in Montreal.

A very comprehensive criminal investigation which involved multiple jurisdictions was conducted. The aunt turned out to be the first wife of the businessman, who was in a polygamous marriage with his second wife, the mother of all seven children in the family. On July 22, 2009, the businessman, his wife, and their oldest son were arrested and subsequently charged with first-degree murder of all four victims.

Inquires by the police indicated that the four victims in the car had been intentionally killed. The evidence did not support the four victims dying in the car, as they appeared to have been killed elsewhere. Covert surveillance had indicated that the father, mother, and son had been involved in killing their children/siblings. The son subsequently admitted that he had been at the scene when the Nissan® entered the water, but said it was an accident.

The motive presented by the prosecution was that these deaths were “honor” killings based upon the three teenage girls having become too “westernized.” The offences have been called “honoricides” by the press.

The businessman, his wife, and son were tried for first degree homicide. The trial lasted over two months and involved witnesses giving evidence in four languages including Dari, the Persian dialect spoken by the defendants. Both parents gave evidence in their defense, but not the son. The jury returned guilty verdicts against all three defendants.

This presentation will discuss how the complex investigation developed, the pathology of the victims, and the concept of “honor killings.”

Homicide, Drowning, Honor Killing

Breakfast Seminar - 2015

BS8 Thomas Krauss Bitemark Breakfast: From *Frye* to *Daubert* — A Change in Legal Standard

*Jeffrey L. Ashton, JD**, Office of the State Attorney, 415 N Orange Avenue, Orlando, FL 32792; and *Adam J. Freeman, DDS*, 22 Imperial Avenue, Westport, CT 06880

The goal of this presentation is to discuss the challenges facing prosecutors in presenting scientific evidence, generally and specifically those faced when presenting new or novel scientific advances. In particular, discussion will encompass the implication of the change in legal standards from *Frye* to *Daubert* as they apply using the State of Florida as an example.

This presentation will impact the forensic science community by providing a more complete understanding of the prosecution of Casey Anthony.

Born on October 3, 1957, in St. Petersburg, Florida, Jeff Ashton studied law at the University of Florida School of Law and became an Orlando prosecutor. In 1987, he was the first lawyer to earn a conviction by introducing DNA evidence into a case. Decades later, he became the head prosecutor of the sensational 2011 Casey Anthony trial. Ashton has written a book about his experiences, *Imperfect Justice: Prosecuting Casey Anthony*, and was sworn in as a state attorney in 2013.

Jeff Ashton worked in a number of divisions that were part of the state attorney's office before winning his first murder conviction in a 1983 trial. While serving as assistant state attorney in 1987, Ashton took on a groundbreaking role: he began working as prosecutor on the trial of a Florida serial rapist, and during the trial, he introduced DNA-based evidence. The case resulted in the first conviction using DNA testing, with such evidence being used regularly thereafter, in cases throughout the country. Three years later, Ashton established his office's homicide division.

For a time in 2002, Ashton was appointed as head of the juvenile division of the state attorney's office, but missed the courtroom and decided to return to prosecuting. Over his decades-long career, he has taken hundreds of cases to trial.

In June 2011, Ashton worked as prosecutor in the highly sensational Casey Anthony trial. Anthony, a young woman from Florida, was accused of murdering her 2-year-old daughter, Caylee Anthony, whose remains were found near the Anthony home. The case received a huge amount of media attention focusing on the Anthony family's back-story, with the prosecution taking the stance that Anthony was guilty of murder, and the defense countering that Caylee's death was an accident that was subsequently covered up.

On July 5, 2011, the jury found Casey Anthony not guilty of first-degree murder, aggravated manslaughter, or aggravated child abuse charges. Anthony was found guilty of charges related to providing the police with false information, and was placed on parole after receiving a fine and credit for time served. Ashton was stunned by the decision.

As he'd intended, Ashton retired from working as prosecutor after the trial and worked part-time at a law firm. In November 2011, Ashton released the best-selling book, *Imperfect Justice: Prosecuting Casey Anthony*, published by William Morrow. In his book, the prosecutor deconstructs the case, including his thoughts on Anthony's Defense Attorney, Jose Baez, and the use of the death penalty.

In 2012, Ashton ran for the state attorney seat in the Floridian counties of Orange and Osceola, against his former supervisor, Lawson Lamar. Ashton won the election and, in early January 2013, was sworn in as a state attorney. That same month, the Lifetime Network aired, *Prosecuting Casey Anthony*, a TV movie based on Ashton's book, starring Rob Lowe as the prosecutor.

Frye, Daubert, Jeffery Ashton

Evening Session - 2015

ES1 Forensic Sciences — Keep It Simple, Stupid!

*J.C. Upshaw Downs, MD**, GBI ME, 925 A Mohawk Drive, Savannah, GA 31419; *Carla Miller Noziglia, MS**, ICITAP, 305 Ascot Drive, Aiken, SC 29803-7833; *Anjali A. Ranadive, JD**, SciLawForensics, Ltd, 1834 Overlook Ridge Road, Brookings, SD 57006; and *Jennifer L.P. Downs, BA**, 11511 Abercorn Street, Ext 182, Savannah, GA 31419

After attending this presentation, attendees will learn a simple paradigm to balance four key elements of practice in order to enhance opportunities for a long-term, successful career.

This presentation will impact the forensic science community by providing a memorable framework to balance the critical areas of education, analysis, reporting/testimony, and ethics.

The career of the forensic science practitioner is arduous. Reflection and simplification may prove beneficial in coping with the myriad stresses inherent in the profession. The requisite training is intellectually challenging, often continuing into graduate and postgraduate studies. Continuing education is essential to stay current with the latest scientific developments and techniques, in addition to exploring potential new research in order to develop improved procedures and protocols. Application of the knowledge base in investigating a particular event is a daily exercise for the forensic caseworker, regardless of discipline.

The awesome responsibility imposed by applying precise analytical methodology while maintaining scientific objectivity which must be balanced with the reality of the significance of the results can prove burdensome. Eventually, the results of the forensic analysis will yield a scientific report which is often presented in court. Sharing the vast wealth of background information with a lay jury by means of unbiased reports and courtroom testimony is an oft underappreciated skill. The convergence of presenting detailed science with conveyance of the essential data while maintaining neutrality requires both sophistication and simplification in communication. Finally, given the gravity of the consequences of the adversarial system and the inherent nature of the casework, the forensic scientist experiences profound ethical challenges during the course of a career. Those successful in the long term are careful to pay heed to the needs of the individual human spirit. Diversions and moderation can help balance the ethics of personal and professional life in order to maximize the individual's potential for overall success.

Thus, the four cornerstones of knowledge, investigation, sharing, and spirit are the bedrock upon which a successful career in the forensic sciences can be structured. Utilizing an entertaining multimedia format, the panel will discuss each of these four elements in order to demonstrate how each might be integrated into a successful whole. These lessons will no doubt prove beneficial to attendees at all points on the career path, from novice to retiree. Ultimately, the foundation will remind all that a successful mantra for forensics is easy to remember — keep it simple, stupid!

Ethics, Testimony, Analysis

Luncheon Seminar - 2015

L1 Fetal Kidnapping by Cesarean Section

*Michael Welner, MD**, 224 W 30th Street, Ste 806, New York, NY 10001; and *Ann Wolbert Burgess, DNSc**, Boston College, 228 Highlands Avenue, West Newton, MA 02465

After attending this presentation, attendees will be aware of the common conflicts and personality qualities of those who commit kidnapping by cesarean section. Attendees will also be informed about the modus operandi of this most peculiar crime. The data will be integrated into recommendations for forensic assessment and public safety.

This presentation will impact the forensic science community by presenting findings from 15 completed and five attempted cases of fetal kidnapping by cesarean section and by providing insights about perpetrators who commit this unthinkable crime so that prevention can play a role in any future research.

The National Center for Missing and Exploited Children (NCMEC), concerned with the abduction of children (birth through six months) by non-family members, has been studying such cases since 1983, focusing on the abductors and violence, and has been providing guidelines for healthcare professionals on prevention of and response to infant abductions. While educational programs for healthcare agencies and hospitals proved successful in deterring abductions from institutions, the number of abductions from nonagency settings and the numbers of infant abductions from non-hospital settings increased. A study of 247 infant abductions over three decades revealed birth mother injury as an important change between the years of 1983-1992 and 1993-2006. The occurrence of fetal abduction by cutting open the mother's abdomen, though rare, has increased. This raises questions as to the motivation for the act, the dynamics in the planning, the lethal intent to secure a baby, the legal outcomes, and the lessons to be learned for prevention.

Fetal abduction involves behaviors that are not well understood or researched. In the first study of its kind, media-reported, non-family cesarean section cases were reviewed. This presentation reports the findings on the 15 completed and five attempted, non-family member cases reported to the NCMEC. Data were obtained from court documents as well as NCMEC records. A number of demographic variables were investigated: perpetrator gender (all female), state the crime was committed in (13 states), year the crimes took place (with the number doubling since 2000), race (varied, with race of the victim mother being consistent with the offender's), and age (most abductors targeted a younger mother, with the offender's age ranging from 19 to 40 years of age). Furthermore, all perpetrators (except one) were in a relationship, more than half already had children, and nine offenders were (or believed they were) infertile.

Several themes were identified across the 15 cases. All abductors lied that they were pregnant, although the motivation for the lie varied. Abductors sought out medical information on childbirth and cesarean sections to prepare for the crime. A critical component of pregnancy simulation is targeting either a "known" mother and gaining her trust or frequenting places pregnant women attended to select a "random" victim mother. For all perpetrators, the murder plan had long been in their mind, and they usually prepared cesarean "kits" in advance; however, the location of the crime varied. In all but one case, the victim mother died, and only ten of the 15 babies survived. This research investigated the psychological defenses employed in each case, and the topics of lying, pregnancy simulation, and capacity to commit murder for personal gain of a newborn while legally sane were critical to this study. Perhaps most important was the underlying issue of fertility as central to the identity of the perpetrator.

This presentation reviews the findings of this study and its implications for public safety and for forensic assessment. Examples illustrating the expression of these peculiar personalities, how they relate to others in their lives antecedent to and following the crime, and lessons from how victims are ensnared — and escape — are also presented.

Female, Fetal Kidnapping, Cesarean

Luncheon Seminar - 2015

L2 The Dating Game Killer: Rodney Alcalá's 40-Year Dance With Death

*Melissa Mourges, JD**, New York County District Attorney's Office, One Hogan Place, New York, NY 10013; *Martha Bashford, JD**, New York County District Attorney's Office, One Hogan Place, New York, NY 10013; *Mark E. Safarik, MS**, Forensic Behavioral Svs Int'l, 10908 Courthouse Road, Ste 102255, Fredericksburg, VA 22408; and *Jonathan Hayes, MD**, OCME, 520 1st Avenue, New York, NY 10016

After attending this presentation, attendees will learn how investigators linked the murders of two women in New York City in the 1970s with a string of California homicides committed by "Dating Game Killer" Rodney Alcalá, and how he came to justice after 40 years.

This presentation will impact the forensic science community by illustrating investigative, forensic, and prosecutorial techniques that turn cold cases into court cases.

What would you think if you picked Bachelor #1 on the Dating Game and he turned out to be a serial killer? That's what happened in 1978 to a contestant who chose Rodney Alcalá as her date. Luckily, that woman's "Spidey-sense" went off after they met backstage and she refused to go out with him.

Alcalá had killed four women by the time he was a Dating Game contestant in 1978; at least three more victims followed. A decade earlier, Alcalá had abducted an 8-year-old California schoolgirl and drove her to his house. A witness called police, who broke down the front door as Alcalá jumped out a back window. Tali Shapiro was naked and near death; Alcalá had choked her by putting a barbell across her throat.

He escaped to New York City and enrolled in New York University's film school under the name John Berger. Then, in 1971, 23-year-old stewardess Cornelia Crilley was found with bitemarks on her breast, raped, strangled, and posed inside her Upper East Side bedroom, but the case remained unsolved. Later that summer, while "Berger" worked at a music camp in New Hampshire, campers recognized his picture on a Federal Bureau of Investigation (FBI) wanted poster. He was extradited for the Shapiro assault and served four years in jail.

He returned to New York, where aspiring actress Ellen Hover made a date with him, writing "John Berger" on her calendar. She disappeared from her Manhattan apartment in July, 1977. Her badly decomposed body was found buried in a Westchester park near the Hudson River almost a year later.

After Hover's disappearance, Alcalá returned to California. Within a span of 20 months, he killed five women: a teenage health aide, a 27-year-old nurse, a 32-year-old secretary, a 21-year-old data processor, and a 12-year-old on her way to ballet class. Each was raped, strangled, and posed; some were beaten, some had bitemarks.

One victim survived; Alcalá had picked up a 15-year-old hitchhiker, drove into the mountains, where he sodomized, raped, and choked her. He let her live when she promised to be his girlfriend.

DNA eventually linked the California attacks. Alcalá was convicted and sentenced to death in 2010. Detectives uncovered hundreds of photos of young women and boys in his storage locker in Seattle and searched for new victims. Meanwhile, the Crilley and Hover cases remained unsolved. Links to Alcalá were made; his fingerprint was on an envelope found beneath Crilley's body and bitemarks on her breast were consistent with Alcalá. In addition, the "Berger" notation on Hover's calendar was linked to his alias.

The Manhattan District Attorney's Cold Case Unit and the New York City Police Department (NYPD) worked to pull together a legally sufficient case to charge Alcalá in those deaths. Retired FBI Senior Profiler Mark Safarik, who worked the original California cases, and the Office of Chief Medical Examiner (OCME) Forensic Pathologist Jonathan Hayes, scoured autopsy reports and crime scene photos for similarities. Investigators found friends and neighbors of the victims, Alcalá's old girlfriends, eyewitnesses, vehicle registrations, toll receipts, decades-old serology reports, and medical and military records. Alcalá's surviving victim relived the horrible details of her ordeal, and the victims' families cried again as they relived the last time they saw their sisters and learned about their deaths. Alcalá was indicted for killing Crilley and Hover. He pleaded guilty to their murders in 2013 and received the maximum sentence. Headlines at the time read, "Judge Weeps as Serial Killer Sentenced." Alcalá was returned to San Quentin where he still lives on Death Row.

Dating Game Killer, Sexual Predator, Cold Case Serial Homicide

W1 Mass Fatality Incidents: An Integrated Approach Workshop

*Christian Crowder, PhD**, Harris County Institute of Forensic Sciences, 1885 Old Spanish Trail, Houston, TX 77054; *Todd M. Howell, MFS**, 92 Cinnamon Way, Magnolia, DE 19962; *Ladd Tremaine**, CMR 402 Box 2323, APO, AE 09180; *Edward A. Reedy, PhD, MD**, Armed Forces Medical Examiner System, 115 Purple Heart Drive, Dover AFB, DE 19902; *Sean A. Swiatkowski, DO**, Armed Forces Medical Examiner System, 115 Purple Heart Drive, Dover AFB, DE 19902; and *Edward Mazuchowski II, MD, PhD**, 116 Purple Heart Drive, Dover AFB, DE 19902

After attending this presentation, attendees will understand how the Armed Forces Medical Examiner System integrates various areas of forensic science in mass fatality incidents. In addition, attendees will have an understanding of how emerging technologies are leveraged in each of the areas.

This presentation will impact the forensic science community by demonstrating an effective and proven approach to integrating various fields of forensic science and emerging technologies in mass fatality incidents.

A mass fatality incident occurs when the local resources that are normally used in response to a fatality event are overwhelmed or have the potential to be overwhelmed. Although the number of fatalities or potential fatalities has been traditionally used as the delineator for a mass fatality incident, other factors such as the circumstances of the event and condition of the local infrastructure must be considered. For example, an explosion where only three individuals are deceased but there is extensive fragmentation and comingling of the remains may warrant the implementation of a mass fatality plan. This situation is exponentially complicated if the explosion is due to a terrorist activity such as a “dirty bomb.” In order to effectively manage these incidents and conduct appropriate medicolegal death investigations it is necessary to have an integrated approach between various forensic science disciplines.

Since its inception, the Armed Forces Medical Examiner System has employed an integrated approach to medicolegal death investigations, in particular to mass fatality incidents. At the location of the incident there is coordination with the local law enforcement agency, investigating agency, such as the Federal Bureau of Investigation, United States Army Criminal Investigation Command, Naval Criminal Investigative Service, or United States Air Force Office of Special Investigations, and mortuary affairs. At the scene, it is necessary to document evidence, decontaminate the remains as necessary, systematically document and recover the remains and personal effects, provide transport and/or temporary storage of the remains, and generate and maintain a chain of custody of all evidence, remains, and personal effects that will be used until final disposition. At the intake area of the autopsy operations site, all of the remains are triaged, photographed by a forensic photographer, and given a unique identifier. The remains are scientifically identified through fingerprint, dental, and DNA comparison. These comparisons require the integration of fingerprint specialists, forensic odontologists, and DNA specialists. Radiographs are performed on all of the remains by radiology technicians and forensic radiologists interpret the images. Examination of the remains is conducted by board-certified forensic pathologists, toxicology samples are taken, and all evidence is collected and released to the investigative agency. Board-certified forensic anthropologists assist in the triage of the remains and are available for expert consultation. The forensic pathologist has the overall responsibility to complete the death certificate and certify the identification of the remains, cause of death, and manner of death. The remains and personal effects are released to mortuary affairs with the appropriate documentation and communication is made with the families.

This presentation will provide an overview of how various areas of forensic science are integrated in mass fatality incidents. These areas include law enforcement, mortuary affairs, medicolegal death investigation, forensic photography, fingerprint specialists, forensic odontologists, DNA specialists, forensic radiology, forensic anthropology, forensic pathology, and forensic toxicology. In addition, the emerging technologies of each field will be highlighted.

Mass Fatality, Victim Identification, AFMES

W2 The Electrophysiology of Impulsive Aggression and Criminal Responsibility

*Alan R. Felthous, MD**, Saint Louis University School of Med, Forensic Psychiatry Division, 1438 S Grand, St. Louis, MO 63104-1027; *Stephen J. Ferrazzano II, JD**, Office of Public Defender, 601 Jewett Street, Ste A, Marshall, MN 56258; *Ghazala Hayat, MD**, Saint Louis University, 1438 S Grand Boulevard, Saint Louis, MO 63104; *Kelly N. Gable, PharmD**, Southern Illinois University at Edwardsville, School of Pharmacy, Edwardsville, IL 62025; and *Matthew S. Stanford, PhD**, Baylor University, 1 Bear Place, #97334, Waco, TX 76798

After attending this presentation, attendees will better understand of the role of an electrical abnormality in impulsive aggression and will appreciate the concomitant normalization of abnormal event-related potentials and impulsive aggressive behaviors.

This presentation will impact the forensic science community by enabling attendees to explain the strengths and weaknesses of impulsive aggression, with its electrophysiological manifestation, in mental defenses against criminal charges.

In the context of criminal responsibility it is difficult to distinguish an irresistible impulse from an impulse not resisted. Yet criminal responsibility presumes some capacity to control one's conduct and impulsive aggression is aggression without the normal level of control. The neurosciences have in recent decades enhanced our understanding of impulsive aggression. Electroencephalograph (EEG) and event related potentials are manifestations of consciousness and intention respectively, of an "electric will" as it were. A measurable biological sign of impulsive aggression, normalize by specific efficacious Anti-Impulsive Aggressive Agents (AIAAs), is the event related potential, P3 in particular. This provides evidence, beyond a subject's self-serving claim, "I could not control myself!" of a mental/emotional/behavioral abnormality with relevance to the so-called volitional component of criminal responsibility.

Event Related Potentials (ERP) are summated responses at the post-synaptic level of pyramidal neurons in the different parts of the brain to sensory, motor, or cognitive stimuli. ERPs can be exogenous or endogenous. The exogenous ERPs are of shorter latency, lower amplitudes, and high frequency. These are evoked by the environment and can be obtained under sedation. While endogenous ERPs of longer latency, higher amplitudes and lower frequency, these are not affected by changes in physical parameters of stimuli. These depend on prior experiences and expectations and are affected by psychological states. Endogenous ERPs are obtained only in awake states. Also related to voluntary action, Bereitschaft potentials, movement related potentials, are recorded over a contralateral sensory cortex in response to movements.

The most common latencies recorded are P3, N1, SW, and CNV. The ERPs can be helpful in dementia, Parkinson's disease, vascular dementia, multiple sclerosis, encephalopathies, and other neuropsychiatric disorders. The P3 abnormalities have been shown in many of these disorders including Down and Turner's syndrome.

With standardizations, ERPs can be helpful in many neuropsychiatric disorders, there are more easily performed as compared to functional MRI scans.

The panel will review neurophysiological biomarker assessments, specific to pharmacotherapy treatment options used for the treatment of impulsive aggression. Biomarker assessments are closely linked to brain physiology and maybe a reasonable representation of pharmacotherapy changes. The electroencephalograph (EEG) abnormalities seen specifically with antipsychotics, anticonvulsants, and antidepressants will be reviewed. The clinical implications of EEG changes in relation to medication efficacy and resistance will also be discussed for schizophrenia, bipolar disorder, and Attention Deficit Hyperactivity Disorder (ADHD).

Aggressive behavior is a major concern in both mental health and criminal just settings. Although pharmacotherapy is often used in the treatment of the violent individual, no medication is presently approved by the United States Food and Drug Administration specifically for such use. It has been suggested that the neurobiological deficits specific to impulsive aggressive behavior may serve as indicators of an ineffective behavioral control system. This presentation will give an overview of studies that have used ERPs as an outcome measure in pharmacotherapy for impulsive aggression.

With this scientific and clinical background on the electrophysiology of impulsive aggression, the format of the panel will change over to a brief discussion of the American Law Institute (ALI) insanity defense and the extreme emotional disturbance defense, followed by a mock direct and cross examination of an expert witness at trial. The extreme emotional disturbance discussion will center on the jury instruction for the State of New York where it is an affirmative defense that can, if successful, reduce a murder charge to a first degree manslaughter conviction. Using a created case to best illustrate the points of this presentation, the mental health professional will provide testimony in support of impulsive aggression, also diagnosed as intermittent explosive disorder, in a defendant charged with

Workshop - 2015

first degree murder. The double mental defense will consist of both the volitional prong of the ALI insanity standard and a version of the extreme emotional disturbance defense respectively. After attendees provide the verdict, the discussion will focus on the strengths and deficiencies of impulsive aggression, where sufficiently severe and abnormal, as a mental defense without the presence of another mental disorder.

Event-Related Potentials, Impulsive Aggression, Criminal Responsibility

W3 Classification of Typewritten Documents

Karen J. Nobles, BA, Forensic Document Examinations, PO Box 411, Pensacola, FL 32591; and Peter V. Tytell, BA*, Forensic Research, LLC, 15 Maiden Lane, Ste 308, New York, NY 10038-4017*

After attending this presentation, participants should have an understanding of the typewriter typestyle classification systems and understand their uses and limitations.

This presentation will impact the forensic science community by providing an update of typewriter typestyle classification systems.

Typewriters, typewriting, and typewritten documents have shown an increase in popularity in recent years. In 2010 in Philadelphia at Bridgewater's Pub in 30th Street Station, the first "Type-In" was organized and held by Mike McGettigan. The popularity of the Type-In has grown, and in recent years they have been held in various locations across the United States, Canada, Europe, Asia, and Australia. A Type-In is an arranged meeting of manual typewriting enthusiasts. A typical Type-In may include the following activities: a typing speed competition; distribution of stationery, envelopes and stamps, followed by a typed letter-writing session; and, the swapping and purchasing of typewriters.

One suspect told investigators, "I saw on TV how the cops can seize your computer and get all of the information off of it, so I bought a typewriter, which I didn't think could be identified or tied to me."

This workshop will enhance and refresh the forensic document examiner's skills in the examination of typewritten documents. The morning session will introduce the attendees to the history of type style classification schemes, including those developed by Ordway Hilton, Dr. David Crown, and by Josef and Bernard Haas. The basic principles for classifying typewriter type styles will be demonstrated and explained.

The afternoon session will cover classification techniques using the WinType classification program, the Haas Atlas of Pica and Non-Pica Typewriter Print, and the Interpol System for Identification of Typewriter Makes Card Index. The WinType program is an update of the original "type" program developed by Dr. Philip D. Bouffard in the late 1980s. Dr. Bouffard's TYPE program was based on the manual typewriter classification systems of the time, and required a DOS-based operating system. It used a searchable database to limit the number of known type specimens that had to be compared with a questioned typewritten text. Unfortunately, the current Windows environment does not allow the original TYPE program to operate correctly.

Numerous practical exercises using the WinType program, as well as other classification systems, will provide a unique hands-on experience. A copy of the WinType database and other valuable reference files will be provided to each attendee.

Attendees will need to bring a laptop computer running Microsoft® Access, or other comparable database program, and a hand magnifier. A small flashlight, or other portable light source, that can be used for additional lighting may also be helpful.

After attending this workshop, participants should have a greater understanding of the history of typewriter type styles classification systems, the principles of classifying type, the typewriter reference material used, and a firm understanding of their limitations.

Typewriter, Typestyle, Classification

W4 Obtaining Successful DNA Profiles From Challenging Samples

*Sudhir K. Sinha, PhD**, InnoGenomics Technologies, LLC, 1441 Canal Street, Ste 307, New Orleans, LA 70112; *John Ballantyne, PhD**, University of Central Florida, Dept of Chemistry, 4000 Central Florida Boulevard, Orlando, FL 32816-2366; *Timothy P. McMahon, PhD**, 115 Purple Heart Drive, Dover Airforce Base, Dover, DE 19902; *Bruce R. McCord, PhD**, Florida International University, Dept of Chemistry, University Park, Miami, FL 33199; *Arthur J. Eisenberg, PhD**, UNT Health Science Center at Fort Worth, 3500 Camp Bowie Boulevard, Fort Worth, TX 76107; *Mark R. Wilson, PhD**, Western Carolina University, Dept of Chemistry/Physics, Forensic Science, Cullowhee, NC 28723; and *Craig O. O'Connor, PhD**, NYC OCME, 421 E 26th Street, New York, NY 10021

After attending this presentation, attendees will understand how to overcome challenges associated with trace and/or degraded forensic DNA samples by using novel DNA extraction, quantification, profiling, and analysis technologies to provide probative results from even the most compromised DNA samples.

This presentation will impact the forensic science community by serving as a forum for disseminating the latest information regarding the analysis of challenging forensic DNA samples. The panel discussion will include information on new DNA testing systems and methodologies for cases where traditional methods do not produce results.

The past 25 years have seen great strides in forensic DNA analysis. Improved evidence collection procedures and technology advancements using the Polymerase Chain Reaction (PCR) process have enabled scientists to provide scientific evidence in criminal cases that were previously unimaginable. Next generation platforms, test systems and methodologies now provide scientists with the tools to evaluate biological samples that consist of degraded, trace, touch and/or contact DNA evidence. Typically forensic DNA samples have multiple challenges including: limited quality, limited quantity, the presence of PCR inhibitors and complex result interpretation. These factors contribute to the difficulty of eliciting meaningful profiles from compromised samples. At present, there is a real need for more robust, highly sensitive, reproducible methods for the extraction, quantification, PCR amplification, typing and interpretation of DNA results when attempting to profile these difficult samples.

Next generation platforms and test systems now provide scientists with tools to evaluate samples consisting of degraded and/or trace DNA with greater efficiency and higher success rates. This panel of subject matter experts will present their research and findings regarding challenging forensic samples and how to overcome issues of degraded and/or low copy DNA as well as new technologies designed to provide probative results from even the most compromised forensic samples. Topics covered in this workshop include improvements in extraction efficiency, optimizing laboratory processing procedures, trace DNA recovery methods, improved methods for DNA quantification, setting thresholds for capillary electrophoresis, novel DNA markers systems and result interpretation issues with challenging samples such as mixtures, and statistic probabilities and allele drop-out. This panel of experts will also discuss case studies, including missing persons and mass disaster identifications.

Topics presented include:

- Optimized processing methods developed and utilized for the identification highly challenged human remains.
- How to set analytical thresholds in the face of new instrumentation and improved STR kits.
- Development and application of trace DNA methods to household dust and touch evidence.
- Novel marker system for analysis of highly compromised DNA samples.
- Analysis of highly degraded missing persons samples.
- Improvements in DNA extraction efficiency from challenging samples such as hair and bone.
- Forensic statistics at the NYC OCME - dealing with complex DNA mixtures, probabilities and dropout.
- World trade center disaster samples 14 years later.

DNA, Degraded, Challenging Samples

W5 Ancestry Estimation in the 21st Century

*Kate Spradley, PhD**, Texas State University, Dept of Anthropology, 601 University Drive, San Marcos, TX 78666; *Joseph T. Hefner, PhD**, Michigan State University, Dept of Anthropology, 355 Baker Hall, East Lansing, MI 48824; *Stephen D. Ousley, PhD**, Dept of Applied Forensic Sciences, Dept of Anthropology, 501 E 38th Street, Erie, PA 16546; *Richard Jantz, PhD**, University of Tennessee, Dept of Anthropology, Knoxville, TN 37996-0720; *Bruce E. Anderson, PhD**, Pima County OME, Forensic Science Center, 2825 E District Street, Tucson, AZ 85714; and *Kathryn H. Haden-Pinneri, MD**, Harris Co Inst Forensic Sciences, 1885 Old Spanish Trail, Houston, TX 77054

After attending this presentation, attendees will: (1) understand methodological and theoretical aspects of ancestry estimation in light of the modern understanding of human biological variation and classification statistics; (2) comprehend the complex population groups within the United States and the best methods and terminology to use when providing an ancestry estimate; (3) recognize the best methods to use for non-metric and metric ancestry estimation; and, (4) foster an understanding of the role played by the cultural profile in medical examiners' offices and the role of the forensic pathologists in ancestry estimation.

This presentation will impact the forensic science community by providing up-to-date methodologies and modern theoretical considerations in ancestry estimation using traditional and novel approaches. Additionally, attendees will be provided with new approaches and solutions to new concerns when confronted with the current population demographics of the United States.

This presentation will focus on multiple aspects of ancestry estimation in the modern era and direct attention to some of the more important considerations necessary when making these estimates. Following a general introduction and a thorough overview of human biological variation and secular change, the focus of attention will be refined to illuminate aspects of ancestry estimations from different viewpoints and multiple forms of analysis. Ancestry estimates by the medical examiner rely on aspects of human biological variation related to, but different from, those used by forensic anthropologists. Understanding how each practitioner can assist each other and appreciating the separate questions answered is necessary and timely, given the changing demographics in the United States. When attempting to identify the remains of an individual from a complex population, we must understand the history of that population and how that history affects population structure. In other words, we need to "know" the population in order to estimate ancestry. Methodological approaches to the estimation of ancestry will also be addressed. These will include comprehensive discussions on metric and non-metric methods of analysis and a thorough exchange of ideas on the traditional and novel statistical methods and theories being used today. While metric and non-metric methods have traditionally dominated forensic anthropological analysis of ancestry, the cultural profile in conjunction with the biological profile, stands as a novel although very important tool for ancestry estimates, particularly in Undocumented Border Crossing (UBC) cases from the southwest where the cultural profile was developed. The cultural profile has been instrumental in the identification of UBCs from Central and South America.

Establishing the ancestry of human remains has been referred to as one of the more difficult aspects of biological profile construction; however, this need not be the case. Our understanding of human variation has changed dramatically since the early days of biological anthropology; in fact, the last quarter-century has witnessed intensification in the methods used to estimate ancestry and in the theoretical considerations of secular change and population specificity of method application. Non-metric traits no longer rely on typological trait lists or extreme trait values supposedly linked to a "race." Metric analysis has likewise experienced a concerted change as our understanding of classification statistics increases and as we acknowledge the need for more reference populations from around the world to represent the true nature of human biological diversity.

Biological profiles generated in a medicolegal setting play an important role in identification, therefore, estimating ancestry is a fundamental component of the biological profile; however, understanding why we can estimate ancestry and the complex factors surrounding ancestry estimation are given little attention in the forensic anthropology literature. Understanding the population history and structure in addition to secular changes in the American population, with particular attention to complex population groups (e.g. Hispanic, American Black), can provide a greater understanding of process of ancestry estimation and can lead to more accurate results. Further, gone are the days of trait lists and typology. The new morphoscopic approach relies on a comprehensive understanding of the traits and their character states, along with proper classification statistics for ancestry estimation. Metric analyses also require more than just rote memorization of landmarks and dated classification statistics. New metric methods, such as machine learning techniques, capture the salient features of geographic ancestries, but may also be used for further refinement at the local population level. These methods require knowledge in the data at hand and in the statistical methods used for classification.

Ancestry, Human Variation, Biological Profile

W6 Practical Homicide Investigation®: Offender-Manipulated Homicide Scenes Relating to Equivocal Death and Staged Crime Scenes

Vernon J. Geberth, MS, PO Box 197, Garnerville, NY 10923; Barbara C. Wolf, MD*, District 5 MEO, 809 Pine Street, Leesburg, FL 34748; and Thomas C. McAndrew, BA*, Pennsylvania State Police, 5933 Derick Drive, Orefield, PA 18069*

After attending this presentation, attendees will have a better understanding of the unique dynamics of offender-manipulated homicide scenes and equivocal death investigations as well as the application of professional homicide investigation and medicolegal analysis of these events.

This presentation will impact the forensic science community by providing and familiarizing forensic scientists and investigators with the art and science involved in the professional examination of homicides and sudden, violent death scenes which have been manipulated by the offender to mislead and thwart the investigation.

Offender manipulated homicide scenes pose a unique problem for the first responders and investigators because these events are equivocal death investigations and as such are open to interpretation. Crime scene and autopsy observations may suggest more than one meaning. The facts may be purposefully vague or misleading as in the case of the “Staged Crime Scene” or where the death is suspicious or questionable based upon what is presented to the authorities.

Such deaths may present as homicides, suicides, accidents, or natural causes and may be altered by the offender to misdirect the investigation through staging of the scene and/or posing or mutilation of the body. They are open to interpretation pending further information of the facts, the victimology and the circumstances of the event.

This workshop will focus on the investigative applications and best practice model of Practical Homicide Investigation® and the medicolegal evaluation of specific equivocal cases as well as the application of forensic pathology to the investigative process to accurately determine the cause and manner of death through a multidisciplinary medicolegal investigation as they relate to the investigation of offender manipulated homicide scenes.

Upon completion of this workshop the participants will have a better understanding of the unique characteristics and dynamics of offender manipulated homicide scenes and equivocal death investigations as well as the application of professional homicide investigation and medicolegal analysis to these events. The participants should better understand the importance of crime scene integrity, the management of the homicide investigations, the processing of the homicide crime scene, as well as the application of the medicolegal investigation specifically as it relates to cause and manner of death and the evaluation of the lethality of injuries and wounds.

Equivocal Death, Victimology, Forensic Science

W7 Challenges in Fire Debris Analysis

Eric Stauffer, MS, Police cantonale Fribourg, Place Notre-Dame 2, Fribourg, FR CH-1700, SWITZERLAND; Reta Newman, BS*, Pinellas County Forensic Lab, 10900 Ulmerton Road, Largo, FL 33778; Julia A. Dolan, MS*, Bureau of ATF, Forensic Science Laboratory, 6000 Ammendale Road, Ammendale, MD 20705; and Douglas E. Byron, BS*, Forensic & Scientific Testing, 275 N Perry Street, Lawrenceville, GA 30046*

After attending this presentation, attendees will better understand the interfering products that can be found in fire debris analysis and how the products make identification of ignitable liquids difficult. Additionally, attendees will become familiar with: (1) different ignitable liquid classes and their chemical characteristics; (2) the effects of the extraction techniques on the recovered ignitable liquid residues; (3) the thought processes used to identify interfering products and ignitable liquids from fire debris samples; (4) the composition of various non-traditional ignitable liquids; and, (5) why different analytical procedures are needed. After this presentation, attendees will be able to return to their forensic laboratories and handle the interpretation of the most difficult fire debris samples.

This presentation will impact the forensic science community by helping attendees better understand and interpret data related to the analysis of fire debris samples, which will lead to a reduction in the number of false negative conclusions and will eliminate false positive conclusions. The direct impact of this presentation on the forensic science community will be a more accurate and reliable science being practiced in crime laboratories.

The analysis of debris and evidence in a fire investigation commonly includes the identification and classification of various types of ignitable liquids. Because the vast majority of ignitable liquids are complex mixtures of hundreds of chemicals, and because many, if not most, of the chemicals present in ignitable liquids are created by pyrolysis or incomplete combustion of common items (carpet, carpet pad, upholstery materials, plastics, etc), proper recognition, identification and classification can be challenging. Couple that with the fact that many substrates inherently contain ignitable liquid residues due to their manufacturing process, an analyst must be able to elucidate the significance of laboratory findings in an appropriate context. The attendees of this workshop will learn how to properly interpret complex chromatograms obtained from the analysis of extracts from fire debris samples. Attendees will first learn the fundamental theory of what fire debris samples are, how they are created, and what stages samples go through before they reach the laboratory. This will provide the necessary foundations for understanding the chemistry of interfering products such as pyrolysis products. The physical and chemical processes leading to the presence of interfering products will be covered.

And, while petroleum based ignitable liquids are the most common, other ignitable products, including bio-fuels and vegetable oils are also of interest in some investigative scenarios. This course will include discussions on the different types of ignitable liquids and their chemical characteristics. Examples of both traditional (mainly petroleum based) and non-traditional ignitable liquids (biofuels, vegetable oils, etc.) that may be encountered will be covered. Presentations will include strategies for recognizing the possible presence of ignitable liquid residues (including physical characteristics of the samples, investigative information, and preliminary chemical findings); the processes associated with optimizing extractions based upon both the sample type and the target analytes; and best instrumental methods and method parameters necessary to identify or classify each type of ignitable liquid. Case discussions with sample data will be included to illustrate the interpretation process.

The type of extraction used and parameters associated with the extraction process used for fire debris analysis can have a significant impact on the data obtained. The influence of the various extraction procedures will be presented with discussion regarding the optimization of sample specific parameters for the most representative extraction. The presentation will include the most common extraction techniques using passive headspace sampling with various adsorbents (activated charcoal, 2,6-diphenyl-p-phenylene oxide, SPME) as well as solvent extraction and simple headspace sampling. Focus will be given to the impact of extraction parameters, primarily surface area of the adsorbent, selectivity of the adsorbent, desorption parameters, and adsorption duration and temperature on the efficacy of the extraction process. Simulated case samples in which extraction technique significantly impacted data generation will be included in the discussion.

The workshop will include practical examples of real case or simulated case samples. Attendees will be encouraged to apply the information provided in the presentations to recognize, identify, classify and/or troubleshoot complex samples using proper interpretative methodology. This element of the workshop will consist of small-group discussions of the data under the close supervision of, and with lively input from, the presenters.

Workshop - 2015

At the conclusion of this workshop, the attendees shall have a better understanding of processes associated with interpreting complex fire debris data starting with assessing the physical characteristics of the samples and the investigative information and culminating with the proper interpretation of the analytical data generated in the laboratory process.

Fire Debris Analysis, Ignitable Liquid Residues, Interpretation of Chromatogram

W8 From Fire Dynamics to Legal Dynamics: Shifted Science and the Criminal Justice System's Response

John J. Lentini, BA, Scientific Fire Analysis, LLC, 88005 Overseas Highway, #10-134, Islamorada, FL 33036; Mark E. Goodson, PE*, 1500 Spencer Road, Denton, TX 76205-5105; James M. Doyle, LLM*, Bassil, Klovee & Budreau, 20 Park Plaza, Ste 1005, Boston, MA 02116; Terry-Dawn Hewitt, LLM*, McKenna Hewitt, 9057 E Mississippi Avenue, #11-206, Denver, CO 80247; and Steven W. Carman, MS*, Carman & Associates Fire Investigation, Inc, PO Box 273, Grass Valley, CA 95945*

After attending this presentation, attendees will grasp the changes that have inundated the fire investigation profession and, to a larger extent, the criminal justice system in which wrongful convictions are sadly a part of the process. Attendees will develop an appreciation of a systematic approach to the prevention of wrongful convictions, much like the National Transportation Safety Board (NTSB) focuses on the causes of train wrecks and plane crashes, not with the idea of blaming someone, but of preventing the next disaster.

This presentation will impact the forensic science community by raising awareness of new science, new standards, and new methods of review on the criminal justice system's handling of fire litigation.

This presentation will explore the changes that have swept through the fire investigation profession in the last few years, both in terms of our understanding of how fires behave and how the courts have come to view fire-related expert testimony.

Recent work by Steven Carman and others has dramatically changed the way fire investigators must view the role of ventilation in fully involved fires. Determining the point of origin of the fire, a fire investigator's core competency, is far more difficult than previously believed. As a result, many fire origin determinations have been called into question. If the fire investigator has not correctly determined the origin, chances are his cause determination is also wrong. The frequent scenario is one where, having determined the wrong origin, the investigator finds no competent source of accidental ignition at the "origin," and using "negative corpus" methodology, declares the fire to have been set.

This presentation will describe the work carried out to attempt to measure the accuracy of origin determinations, and to evaluate the utility of fire patterns in determining the correct origin.

As this new knowledge percolates through the fire investigation community, the legal community has learned new ways of challenging the reliability of fire investigation opinions. Terry-Dawn Hewitt will describe the "perfect storm" now enveloping fire investigators because of Daubert challenges, the National Academy of Sciences Report (NAS), changes in NFPA 921 and 1033, and recent court decisions.

Several cases will be reported where individuals served long prison sentences as a result of being convicted for setting fires that were actually accidents, and will provide some of the legal decisions that move beyond "ineffective assistance of counsel" and "new evidence" theories, and actually embrace the shifted science and fire investigation.

Examination of errors in the criminal justice system will be discussed, including faulty arson determinations, using an approach similar to that used in the medical and transportation industries. "Sentinel event" analysis looks carefully at the train wreck that is a wrongful conviction, but not with the sole intent of finding someone to blame. When people act inappropriately, it is often not simply a result of a "bad apple." Often the cause is a system that encourages bad behavior, or fails to catch it.

Finally, the Scientific Review Board set up by the Texas State Fire Marshal in the wake of the Forensic Science Commission's review and recommendations resulting from the investigation of the Willis and Willingham cases will be described. The new Texas Fire Marshal, Chris Connealy, set up the Board to retroactively examine the arson convictions of individuals serving time in Texas prisons. Several cases reviewed by the committee have been found to not stand up to the standards in place today.

Shifted Science, Ventilation, Conviction Integrity

W9 Forensic Anthropology and Cold Case Investigations: Breaking the Ice

*Erin H. Kimmerle, PhD**, University of South Florida, Dept of Anthropology, 4202 E Fowler, SOC 107, Tampa, FL 33820; *Gregory E. Berg, PhD**, JPAC-Central ID Laboratory, 310 Worcester Avenue, Joint Base Pearl Harbor-Hickam, HI 96853-5530; *George D. Kamenov, PhD**, University of Florida, Dept of Geological Sciences, 241 Williamson Hall, Gainesville, FL 32611; *Jose P. Baraybar, MSc**, EPAF, Av Mello Franco, #341, Jesus Maria, Lima 11, PERU; *Greg Thomas, BA**, Hillsborough County Sheriff's Office, 2224 N Falkenburg Road, Tampa, FL 33619; *Darren Norris, BA**, Sumter County Sheriff's Office, 1010 N Main Street, Bushnell, FL 33513; *James Holmes, BA**, International Homicide Investigators Association, Wisconsin Dept of Justice, Division of Criminal Investigation, PO Box 7857, Madison, WI 53707-7857; and *Liotta N. Dowdy, BS**, University of South Florida, Dept of Anthropology, 4202 E Fowler Avenue, SOC 17, Tampa, FL 33620

The goal of this presentation is to provide training specific to long-term unsolved cases in the areas of forensic anthropology and archaeology, imaging, human identification, and geochemical profiling. This workshop is relevant for anyone in homicide investigations, forensic science, or forensic anthropology working in the United States or internationally.

This presentation will impact the forensic science community by providing an in-depth exploration of a range of new tools and an integrated approach to investigating previously unsolved or long-term cases. The integration of scientific experts into homicide investigations provides an array of evidence and investigative leads that help increase case solvability.

Since 1960, the homicide rate in the United States of America has remained relatively constant; however, significant changes have been made in the professionalization and development of resources available to homicide investigators in the areas of national data and reference banks, innovative forensic tools, forensic imaging, chemical and elemental isotope analysis, and crime scene processing. Moreover, there is a renewed commitment to addressing the problem of long term unsolved or cold cases and the use of new tools and technologies improving the solvability rate.

Research on cold cases, why some cases remains unsolved, and the best approaches utilized to increase their success rate is largely lacking in the scientific literature; however, one suite of tools that is rapidly becoming part of homicide investigations comes from forensic anthropology which offers investigators a range of services, research, training and professional development in human identification, facial imaging, living person age estimation, clandestine grave search and recovery, grave excavation, trauma analysis, and expert testimony.

Homicide cases in which the victims are unknown are the hardest to solve and make up a significant portion of the unidentified persons pool in the United States. Increasingly, anthropologists are also used by law enforcement to assist at the crime scene with human identification, imaging, and media outreach. The purpose of this presentation is to provide training specific to longterm unsolved cases and is relevant for anyone in homicide, forensic science, or forensic anthropology. Experts from anthropology, geochemistry, and homicide investigations will discuss current trends for methods and case analysis in several key areas: (1) cold case analysis: opening pandora's box; (2) witness interviews and issues of episodic memory; (3) crime scene and field methods: from excavation to remote sensing; (4) forensic anthropology methods of ancestry and imaging; (5) geochemical methods to track mobility, birth origins, and diet; (6) public outreach: using media as a tool to bring in leads; (7) case management: when the years pass by; and, (8) trends and opportunities in education and training in cold cases.

Over the past four years, a service oriented research initiative, the Tampa Bay Cold Case Project, has brought the University of South Florida Forensic Anthropology Laboratory together with local medical examiner departments and law enforcement agencies throughout the region. Through this initiative, anthropologists work together with homicide detectives, criminalists, forensic laboratories, and other scientists to systematically go through unsolved cases, dating from 1940 - present and have created a network for collaborators, called the International Consortium for Forensics, Anthropology, and Human Rights (ICFAHR) (www.icfahrf.org). This partnership has been formalized between University of South Florida, the Hillsborough County Sheriff's Office, and the National Center for Missing and Exploited Children to provide training and technical assistance to current and past cases and serves a model for regional networking and service training.

The methods and techniques for this initiative, the ways in which similar models could be established in other regions, and successful case study examples are discussed. From locating buried remains in clandestine graves to identification and prosecution strategies; cold case investigations are discussed from a multitude of perspectives.

W10 NamUs: The Results of Forensic Collaboration

*Steven C. Clark, PhD**, 124 Elm Street, Big Rapids, MI 49307; *Joanna L. Collins, MFS*, 20079 Stone Oak Parkway, Ste 1105-215, San Antonio, TX 78258; *Randy L. Hanzlick, MD**, Fulton County Medical Examiner Center, 430 Pryor Street, SW, Atlanta, GA 30312; *Charles M. Heurich, MFS**, National Institute of Justice, Dept of Justice, OJP, 810 7th Street, NW, Rm 7204, Washington, DC 20531; *B.J. Spamer, MFS**, NamUs/UNT Health Science Center, 3500 Camp Bowie Boulevard, Fort Worth, TX 76107-9964; *Daniel J. Warren, MS**, 4700 Terminal Drive, #1, Fort Myers, FL 33907; *Brenda Galarza, BA**, National Center for Missing and Exploited Children, 699 Prince Street, Alexandria, VA 22314-3175; *Jeffrey M. Jentzen, MD**, University of Michigan, 300 N Ingalls, NI2D19 - SPC 5452, Ann Arbor, MI 48109; *John E. Filippi, DDS**, 86 Ginger Cove Road, Valley, NE 68064; *Emily A. Craig, PhD**, 244 Victoria Way, Georgetown, KY 40324; *Bruce E. Anderson, PhD**, Pima County OME, Forensic Science Center, 2825 E District Street, Tucson, AZ 85714; *Ronald Brunelli**, 100 Elizabeth Blackwell Street, Syracuse, NY 13210; and *Elizabeth A. Murray, PhD**, College of Mount St Joseph, Dept of Biology, 5701 Delhi Road, Cincinnati, OH 45233-1670

After attending this presentation, attendees will: (1) learn about the history of the National Missing and Unidentified Persons System (NamUs) and the various NamUs user types as well as the manner in which NamUs receives and validates its case data; (2) understand how the NamUs databases interact to produce potential matches; (3) realize how case exclusions are made; and, (4) grasp the importance of the “public user” to the success of NamUs.

This presentation will impact the forensic science community by increasing the attendees’ ability to enter cases into the NamUs system and participate in the investigation or tracing of missing and unidentified persons cases nationally. The skills and knowledge obtained in this presentation will assist attendees in communicating with other forensic investigators on cases of missing and unidentified persons regardless of jurisdictional boundaries.

The National Missing and Unidentified Persons System (NamUs), is an electronic clearinghouse for cases involving missing and unidentified persons. NamUs is a free, online, technological resource that can be searched by medical examiners, coroners, forensic scientists, law enforcement officials, and the general public seeking to locate missing persons, or identify those individuals who remain unidentified in morgues across the United States. This workshop will present information highlighting the system’s development, management and the many application strategies used by forensic investigators who regularly use the system as an investigative tool. All workshop attendees will have the option of becoming NamUs “registered users” after the AAFS workshop.

NamUs consists of three linked databases: one populated with information about missing persons (NamUs-MP), one populated with information obtained from the discovery and examination of the remains of unknown persons (NamUs-UP), and the third populated with those individuals who remain unclaimed even after identification is confirmed. Through interactive queries between these three databases, profiles of missing persons can be compared with profiles of unidentified decedents, and vice versa. Unclaimed case information is regularly posted by popular search engines and used by individuals conducting genealogy research who find additional next-of-kin and communicate with medical examiner and coroner offices regarding this information.

Data about missing persons can be entered into the NamUs system by registered public users (including relatives of a missing person), registered law enforcement officers, registered members of clearinghouses, and NamUs staff members. The profiles of unidentified persons are entered into the NamUs system by registered representatives of coroner’s and medical examiner’s offices, some registered forensic scientists, and NamUs staff members. Users of the NamUs-MP and NamUs-UP systems are allowed differential access to information and data entry, such as through viewing and/or editing privileges that are assigned by NamUs administrators. Unclaimed cases may be entered into the system by medical examiner/coroner offices or automatically transferred from the unidentified persons system to the unclaimed system.

Members of the general public can view selected information within all NamUs databases without registration; however, their access to any confidential information about a missing person is restricted, as is their ability to view certain details about unidentified persons. Even after registration, access to some information is completely denied to public users, such as details about a case intended solely for the eyes of law enforcement personnel or medicolegal investigators. Despite some limitations, NamUs is the first government-sponsored website of its kind to allow the general public to view the profiles of missing persons, the unidentified and the unclaimed dead.

Missing, Unidentified, Unclaimed

W11 RADid: Using Radiologic Technologies to Identify Unknown Decedents

Gary M. Hatch, MD*, University of New Mexico, Rad-Path Ctr for Forensic Imaging, MSC 07 4040, 1101 Camino de Salud, NE, Albuquerque, NM 87102; Sharon M. Derrick, PhD*, Harris County Institute of Forensic Science, 1885 Old Spanish Trail, Houston, TX 77054; Jamie Elifritz, MD*, University of New Mexico, Diagnostic Radiology, MSC-10 5530, Albuquerque, NM 87131; Patricia M. Flach, MD*, Winterthurerstrasse 190/52, Zurich, SWITZERLAND; Chandra Gerrard, BS*, Office of the Medical Investigator, Rad-Path Ctr for Forensic Imaging, 1101 Camino De Salud, NE, Albuquerque, NM 87131; Sam W. Andrews, MD*, Office of Medical Investigator, 1101 Camino de Salud, NE, Albuquerque, NM 87102; and Kurt B. Nolte, MD*, Radio-Path Ctr for Forensic Imaging, Office of Medical Investigator, MSC07 4040, 1 University of NM, Albuquerque, NM 87131-0001

After attending this presentation, attendees will understand: (1) the role of radiography and advanced Radiologic Imaging (RADid) in the process of decedent identification; (2) techniques for performing high-quality imaging and creating 3D images and strategies to be able to use these images to make successful identifications; (3) anthropologic approaches to RADid; (4) the need for interdisciplinary collaboration; and, (5) the evolving nature of the evidence basis and standards for RADid.

This presentation will impact the forensic science community by enhancing the ability of practitioners to perform RADid, solidifying awareness of the scientific underpinnings of the methodology, and fostering the interdisciplinary collaboration necessary to ensure the most appropriate methods are considered in any given case. The overall goal is to increase the use of these valuable techniques and, in so doing, increase the number of identifications that are successfully made in the medicolegal death-investigative community.

Forensic pathologists and other forensic practitioners are well aware of the legal and ethical imperatives to identify the dead. Identification using RADid is a well-recognized and perhaps underused method to accomplish this task. Postmortem radiographs, the historical workhorse for RADid, require special attention to technique and positioning to enable successful comparison with Antemortem (AM) studies. The incorporation of advanced imaging modalities in medicolegal death investigation, such as Postmortem Computed Tomography (PMCT), offers new possibilities for RADid. Image data sets generated by PMCT can be rendered and oriented to match almost any AM radiologic study. When comparing to AM radiographs, images replicating the appearance of radiographs can be generated using thick slab multi-planar reformatting in the correct orientation (dubbed “pseudo-radiographs”). Similar images that mimic the orientation and field of view of dental radiographs and orthopantograms can be created, which may facilitate dental identification. Familiarity with these techniques can enable forensic practitioners without Computed Tomography (CT) scanners to create pseudoradiographs from antemortem CT data, for comparison with postmortem radiographs. These techniques are straightforward to master and will be demonstrated during the workshop.

Forensic anthropologists are increasingly using PMCT in addition to standard radiograph comparison for ID investigations. A number of traditional anthropologic measurements can be made from planar or 3D CT reconstructions. These measurements can be used to characterize the biologic profile, potentially narrowing the search for AM records, excluding potential identities, or selecting cases for more detailed anthropologic analysis. Additionally, a new Computer-assisted RADid method using sophisticated shape matching software (CADI) is under development.

A wide array of anatomic and pathologic features are used for RADid comparison including: normal and variant anatomy, presence of new or old disease and foreign bodies. The range of capabilities for decedent identification, and the advantages and disadvantages of RADid will be demonstrated through specific case examples. Techniques applied in this process bridge the technical expertise and knowledge bases of several disciplines. Therefore, collaboration between many types of forensic experts is optimal. Advanced imaging is ubiquitous in medical facilities throughout the United States, but is rare in this country’s medical examiner or coroner’s offices. Specific strategies detailed in this workshop will address the perceived lack of access to advanced imaging in the forensic community.

Identification, Forensic Radiology, Postmortem Computed Tomography

W12 Implementing and Evaluating 3D Technology in a 2D World

Heather J. Seubert, MS, FBI Laboratory, Firearms/Tool marks Unit, 2501 Investigation Parkway, Quantico, VA 22135; Deion Patrick Christophe, MS, 100 N University Drive, Box 203, Edmond, OK 73034; Derrick McClarin, MSFS*, 6034 Forest Lakes Cove, Sterrett, AL 35147; Erich D. Smith, MS*, 2501 Investigation Parkway, Rm 4340, Quantico, VA 22135; Jennifer L. Stephenson, MSFS*, Federal Bureau of Investigation, 2501 Investigation Parkway, Quantico, VA 22135; and Paula H. Wulff, JD*, 3201 Russell Road, Alexandria, VA 22305*

After attending this presentation, attendees will have an understanding of the principles behind each of the technologies presented and the strengths and weaknesses that have been observed. The theory of use, method development, maintenance, and applications within the field of firearms/tool marks will be discussed. The presentation will focus on the studies that have been conducted, evaluation of the data generated, and the potential impact these technologies will have in the discipline of firearms and tool marks.

This presentation will impact the forensic science community by expanding the knowledge-base regarding the use of newer technologies in the forensic firearms/tool marks setting.

The current methodologies used in the firearms/tool marks discipline can be traced back to the early work of J. Howard Mathews, Calvin H. Goddard, and James Hatcher from the 1920's. In these early days of research, many of their methods showed a close parallel to existing technologies that relied upon measurements and illumination techniques. The same question continues to motivate the practitioner to determine whether or not a bullet or cartridge case could be "identified" to a particular firearm. Even before the arrival of the comparison microscope, a match could be determined through the use of a filar micrometer, which was simply a special device placed at the top of a compound microscope that contained a scale and a cross hair, which moved along a scale. Another method used was the method of interchange. This method depended upon an illumination technique which involved a long camera set-up with a short lens. It was also during this time that the stereophotomicrograph was introduced. This system enabled illumination from all directions and was simply a stereo camera on a binocular microscope which allowed for a 3D view of an object and it was realized then how troublesome vibrations could be to capturing these types of images. Now, almost ninety-years later, novel instruments for measuring and illumination can be used to highlight areas on bullets and cartridge cases to a level beyond the 2D world. This workshop will present the work that has been conducted using the Sensofar instrument capable of confocal microscopy, interferometry, and focus variation techniques and the intercomparison of that data, highlighting the strengths and weaknesses of the system. Results of the validation work generated using the TopMatch-GS3D Imaging and Analysis System will be presented highlighting the strengths and weaknesses of the system. Validation work that has been conducted on the Alicona Infinite focus system, the integration of this system for the collection of general rifling characteristics measurements on bullets, and the implications that have been seen for updating the Federal Bureau of Investigation's (FBI) General Rifling Characteristics Database (GRC) will be presented.

This presentation will present the evaluation/validation work that has been conducted on the Sensofar® Instrument, TopMatch-GS™ 3D Imaging and Analysis System, and the Alicona® Infinite Focus® microscope. As a result of these validation experiences, an overview of the necessary validation processes that a laboratory should consider when planning to incorporate new technologies in today's forensic laboratories will be provided as well as how to set up a training program for personnel conducting analyses with these systems. An introduction on how to report the results generated from these methodologies will be presented as well as how to approach court challenges and effectively articulate these technologies and interpretation of results in a court of law.

Topography, Ballistics, Individual Characteristics

W13 The Examination of Skillfully Simulated Signatures

F.L. Jim Lee, Jr., MS, PO Box 207, Eden, UT 84310; Kevin P. Kulbacki, MSFS, Osborn & Son, 1273 Bound Brook Road, Ste 15, Middlesex, NJ 08846; Linton Mohammed, PhD, Forensic Science Consultants, Inc, 433 Airport Boulevard, Ste 406, Burlingame, CA 94010; Peter V. Tytell, BA*, Forensic Research, LLC, 15 Maiden Lane, Ste 308, New York, NY 10038-4017; and Brenda N. Lanners, BS*, San Diego County Sheriff's Regional Crime Lab, 5255 Mount Etna Drive, San Diego, CA 92117*

After attending this presentation, attendees will be able to examine and give opinions on signatures that may be genuine or the product of skillful simulations. Attendees will learn the requirements for a skillful simulator and the characteristics they should look for in the examination of a signature that may have been skillfully simulated.

This presentation will impact the forensic science community by making attendees more aware of the features that may be present in a skillful simulation and, therefore, increasing the examiner's reliability and accuracy in determining the authenticity of signatures.

In the examination of a signature on a document to determine its authenticity, trained forensic document examiners are exposed to document case problems that include such questioned signatures on wills, contracts, log books, checks, financial forms, and other documents. The characteristics and features of simulation may include poor line quality, tremor, lack of variation in pen pressure, hesitations, unusual pen lifts, patching, and retouching of the signature; however, in simulations that have been skillfully executed, these flags may be absent and the examiner may have some difficulty in spotting the flaws in the questioned signature. Such signature authentication problems that may involve a skillful simulation can pose a difficult task for an examiner to render a correct conclusion as to its authenticity.

This workshop will focus on the examination process of questioned and known signature samples and their evaluation, leading to the opinion as to the authenticity of the questioned signature that may be genuine or skillfully simulated. Signature problems of this kind are challenging and require the forensic document examiner to properly assess fine and subtle writing characteristics that are indicative of simulation or are the product of natural handwriting variation. Technical application and proper interpretation of authenticating questioned signature samples to determine whether a signature is genuine or a skillful simulation will also be addressed and further discussed. Attendees will discuss the types of opinions that may be expressed in such examinations.

Upon completion of this workshop, the attendees will have a better understanding of authenticating questioned signatures that may be genuine or simulated. The attendees will also learn about the requirements for a person to be a successful simulator and best practices when examining signatures for authentication. The participants should be able to better understand the strengths of opinions that can be rendered in these types of examinations and the pitfalls that lay in wait for the unwary examiner.

Forensic Science, Document Examination, Signature Examination

W14 On the Leading Edge of Forensic Science

Zeno J. Geradts, PhD*, Netherlands Forensic Institute, Ministry of Justice, Laan van Ypenburg 6, Den Haag, SH 2497 GB, NETHERLANDS; Howard A. Harris, PhD, JD*, University of New Haven, Forensic Science Program, 300 Boston Post Road, West Haven, CT 06516; Richard Vorder Bruegge, PhD*, FBI, OTD, Bldg 27958A, Pod E, Quantico, VA 22135; Gerda Edelman*, Netherlands Forensic Institute, Laan van Ypenburg 6, The Hague, 2497 GB, NETHERLANDS; Ronald Prins, MS*, Fox IT, Olof Palmestraat 6, Delft, AE 26160, NETHERLANDS; and Jurrien Bijhold, PhD*, NFI, Laan van Ypenburg 6, Den Haag, AE 2497 GB, NETHERLANDS

The goal of this presentation is to describe how new developments might impact forensic scientists in their work. Practical examples will be presented.

This presentation will impact the forensic science community by providing an overview of some of the new developments in forensic science and by opening a forum for the discussion of issues that arise regarding such developments.

A wide variety of developments that will soon impact forensic science have been identified within the Think Tank Committee of the Forensic Sciences Foundation, Inc. These range from developments in facial comparison systems, labs on a chip, cloud forensics, drone forensics, cybercrime (including hacking medical devices such as insulin pumps), bitcoins, and augmented reality to 3D printing and even printing DNA for storage of information or making a clone of Van Gogh's ear based on DNA.

The workshop will discuss the advantages and limitations of facial comparison systems possibilities. While there are many publications on automated systems describing their efficacy, questions remain on how well they perform in reality, especially in uncontrolled conditions.

Another focus of the workshop will be on new developments in drone forensics. Proper evidence collection protocols will be discussed.

Within big data and cybercrime forensics several new methods have been developed for analyzing huge amounts of data within the first 24-hours after a crime has occurred. The processing and storage of large amounts of data as well as indexing it in a secure and transparent way to address, while also privacy related issues are the cornerstones of these systems. The workshop will also address cybercrime related issues with body nets (where body sensors are connected to the internet) as well as extracting evidence from other devices such as insulin pumps.

In the last decades, hyperspectral imaging techniques evolved from remote sensing and airborne applications, and are now finding their way into forensic investigations. Hyperspectral imaging enables the non-destructive visualization of chemical differences within the original context, and has proven its value in various forensic applications, e.g. ink comparisons and fingerprint detection. Recent advances in hyperspectral imaging technology enable the development of portable and fast image acquisition systems, motivating a shift from forensic laboratories to the crime scene. In the future, all crime scene investigations could start with a complete spectral scan to record the optical properties in the visible wavelength range, the near infrared and the thermal infrared. This provides investigators with information invisible to the human eye. In this presentation, forensic hyperspectral imaging applications are reviewed and possible future applications are discussed.

A number of forensic applications of virtual and augmented reality have been proposed and tested, such as virtual scene tours, serious gaming, scenario testing and communication. An overview is given of applications that have been tested so far. For every application, a short explanation will be given on the technology and its usability. Finally, preliminary results of a usability study being performed by the Netherlands Police, the University of Delft, and the Netherlands Forensic Institute, will be presented.

Issues with 3D printers and new possibilities for consumer printers will be discussed. The possibilities for making counterfeits and firearms are many. Forensic investigation of 3D printers differs from 2D printers and finding a link between the printer and the material can be more complicated. The next generation of 3D printers is with programmable matter, which has the ability to change the physical properties (density, shape, etc.) in a programmable way, based on user input or autonomous sensing.

Wearable Sensors, Future Developements, Impact

W15 Clinical Toxicology of the Poisoned Patient

Barry K. Logan, PhD, NMS Labs/CFSRE, 3701 Welsh Road, Willow Grove, PA 19090; Robert A. Middleberg, PhD, NMS Labs, 3701 Welsh Road, Willow Grove, PA 19090; Paul Wax, MD*, University of Texas Southwestern, 5323 Harry Hines Boulevard, Dallas, TX 75390; Jeffrey Brent, MD, PhD*, University of Colorado, School of Medicine, 2555 S Downing Street, Denver, CO 80210; and Jay L. Schauben, PharmD*, University of Florida Health Science Center, Dept of Emergency Medicine, 655 W 8th Street, Box C-23, Jacksonville, FL 32209*

After attending this presentation, attendees will be able to describe the process used to evaluate, triage, and treat patients in the emergency room. Attendees will be able to identify situations where consultation with a clinical or medical toxicologist can benefit an investigation and find new resources available through medical toxicology professional organizations to support their investigations.

This presentation will impact the forensic science community by creating better understanding between forensic science professionals and their counterparts who treat living patients prior to their deaths.

Medical toxicology is the branch of medicine that is concerned with the diagnosis and treatment of the poisoned patient. Forensic toxicology, on the other hand, deals with the identification of toxic substances in fluids and tissues and the subsequent interpretation of the findings. While on the surface, the two fields seem mutually exclusive, there is often overlap, especially in the interpretive aspects of findings. Questions as to who should be doing what in related matters can arise and create an aura of confusion and, at times, unfortunate dissension despite clear educational and practice differences.

Individuals involved in the diagnosis of the poisoned patient include both physicians and pharmacists who have received appropriate training. Often, initial assessment of the poisoned patient is accomplished through poison control centers. These centers are manned by professionals who use their knowledge, education and experience, as well as accumulated data, to triage a given situation. Decisions can lead to protocols ranging from no treatment to emergent care. Alternatively, the poisoned patient may appear in the emergency room of a hospital where treatment is sought. Specially trained medical toxicologists are often consulted to diagnosis the patient and plan a course of action. While the majority of hospital laboratories are equipped to analyze for a small set of potential poisoning agents, forensic toxicology laboratories are often geared to analyze for a more diverse set of compounds that can assist in the diagnosis of the poisoned patient.

The outcomes of poisoning can range from complete recovery to death. Forensic toxicologists are often involved in the analysis of fluids and tissues from individuals who have died as a result of poisoning. The practice of forensic toxicology includes both analytical and interpretive components, with the latter representing an assessment of the role of an agent(s) in the death. Often, such conclusions have medicolegal impact. Additionally, forensic toxicologists are involved in the analysis of body fluids for purposes of human performance issues. Interpretation of the findings often impacts legal proceedings.

It is not uncommon for medical and forensic toxicologists to find themselves as opposing experts with both claiming ranking privilege. The arguments from both sides are often convincing in support of each profession. It is clear, however, that educational and experiential differences exist between both parties. Who then, is in a better position to assist in matters regarding the poisoned or impaired individual?

This workshop will provide an overview of the similarities and differences between the medical and forensic toxicologist through their approaches to the poisoned or impaired patient. The roles of each profession in respect to medicolegal issues will be highlighted followed by a discussion on how the two fields together bring synergies to investigations involving the poisoned or impaired patient that either alone, by definition, cannot attain.

Poisoning, Overdose, Medical Toxicology

W16 Your Attention, Please! — A Public Speaking Skills Workshop

Thomas P. Mauriello, MFS, 8775 Teresa Lane, Laurel, MD 20723; Lynne M. Yates, BA, US Department of Defense, 15008 Timberlake Drive, Silver Spring, MD 20905; Frank Horvath, PhD, National Academy for Credibility Assessment, 7540 Pickens Avenue, Fort Jackson, SC 29207-6804; and Laura R. Ellsworth, MFS, 15600 Everglade Lane, #102, Bowie, MD 20716*

The goal of this presentation is to present an oral communications-skills workshop for forensic science students and professionals that will: (1) present more than 55 oral communications learning tools that attendees will be able to implement immediately; (2) facilitate thought and ideas for an effective, entertaining, and strategically planned oral presentation; and, (3) demonstrate how to be customer-focused on your audience.

This presentation will impact the forensic science community by educating attendees to the fact that just being an expert in your field does not provide you with the additional skills necessary to present material in an effective manner. Strong and clear oral communication is paramount in the forensic sciences field to present legal and scientific information in a manner that can be heard, understood, and remembered by listeners. This presentation provides attendees with more than 55 learning points that can immediately be implemented to make a difference in how information is presented in the classroom, courtroom, or working environment.

“Most people would generally agree that a great deal — probably most — of the presentations we have to sit through in the business world are awful. They are all too often passionless, boring, and dense with unreadable PowerPoint slides.”¹

Whether you speak to one or 1,000; are comfortable or terrified with public speaking; whether you have been speaking for many years or just a beginner; “Your Attention Please! — A Public Speaking Skills Workshop” will improve your presentation skills through strategic planning, preparation, and performance. Techniques for speaking in all settings with confidence, choosing the right audio-visual technologies, and dealing with questions from an audience, for example are explained clearly to help the participant develop their presentation skills. Fifty-five proven effective presentation tools will be presented, demonstrated, and provided to each participant who attends this workshop. Knowing your subject does NOT guarantee a successful presentation. Aristotle, who many recognize as the Father of Public Speaking and Forensic Debate said, “It is not enough to know what to say, one must know how to say it.” This short four hour workshop focuses on technique and the recognition that, “a speech is composed of three factors — the speaker, the subject and the listener — and it is to the last of these that its purpose is related.”²

Dr. Joseph Sommerville’s, *The Seven Deadly Sins of PowerPoint Presentations*, will be discussed and positive steps will be presented to take advantage of the benefits of PowerPoint presentation software, rather than be a victim or suspect to “death by PowerPoint.”³ Visuals (slides) should augment the spoken word, not be in place of it. Slide development and the use of “Mindmapping,” will be taught to create clear and dynamic visuals that help the speaker be “heard, understood, and remembered.”⁴

So reduce the fear, embarrassment, and agony of public speaking; or increase your repertoire of oral communications skills in the classroom, courtroom, or conference room. This training experience guarantees that you will gain a wealth of knowledge that will “make a difference.”

This technique helps you generate ideas for presentations faster and with greater flexibility while encouraging more spontaneity and originality in delivery.

Public Speaking, Oral Communication, Speaking Skills

W17 Quality Assurance in Human Identification

Vincent J. Sava, MA, JPAC-CIL, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853; Thomas D. Holland, PhD*, DoD JPAC-CIL, 310 Worcester Avenue, Joint Base Pearl Harbor-Hickam, HI 96853; John E. Byrd, PhD*, 95-033 Hokuwa Street, #51, Mililani, HI 96853-5530; Bradford Byrnes, LLM*, 310 Worcester Avenue, Joint Base Pearl Harbor-Hickam, HI 96853; and Stephanie R. Ah Sam, MS*, JPAC-CIL, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853*

After attending this presentation, attendees will be able to understand the basic quality assurance principles and measures applicable to human identification. Attendees will learn the unique challenges faced by professionals involved in human identification when striving to have their facilities, procedures, and casework meet the standards demanded by the criminal justice and medicolegal systems. Attendees should be able to utilize the material presented to formulate a quality assurance program for their organizations.

This presentation will impact the forensic science community by demonstrating how quality assurance in forensic laboratories and forensic programs have led to objective and measurable standards of performance that ultimately strengthen and elevate the forensic profession as a whole.

Quality Assurance Programs (QAP) in forensic laboratories and activities have been a growing trend over the past decade. The publication of the National Academy of Sciences Report — *Strengthening Forensic Science in the United States: A Path Forward*, and its recommendations have made quality assurance programs and accreditation an increasing priority for forensic human identification laboratories. Since 1999 the Joint POW/MIA Accounting Command (JPAC), Central Identification Laboratory (CIL) has implemented a stringent QAP to ensure the scientific integrity of its casework. The CIL's QAP ultimately led to its accreditation by the American Society of Crime Laboratory Directors Laboratory Accreditation Board (ASCLD-LAB) in 2003 — the first forensic skeletal identification laboratory so credentialed. In 2008 and again in 2013, the CIL was re-accredited under the ASCLD-LAB International Program using ISO 17025 Criteria.

The goals and objectives of this workshop are to introduce the attendee to the CIL's QAP and to convey the lessons learned resulting from its implementation and growth. The workshop begins with an overview of the CIL, its mission, and QAP. A video of the CIL's mission and operations is presented. In the latter, the concept of the scientific integrity of the CIL is discussed followed by a summary of the "Surety" model of quality assurance.

Attendees will become familiar with each measure that comprises the surety model of quality assurance. The importance of integrating and synchronizing all of the surety measures discussed during the workshop is continually stressed.

Issues that are currently at the forefront of forensic quality management are presented. These include: professional qualifications and development; ethics; research and development; validation of technical procedures; uncertainty of measure; and, data management; and, information release.

Infrastructure and support considerations necessary for a successful QAP are also presented. Surety measures addressed include, but are not limited to: desired qualities of a laboratory manual and other vital documentation and their control; adequacy and safety of laboratory facilities; purchasing and contracting for laboratory services and supplies; policies and procedures conducive to a positive work environment; customer service programs and complaint procedures; evidence management and security; and, training and professional development.

Gathering and interpreting evidence discusses quality assurance measures directly related to field operations and trace evidence casework. These surety measures include: peer review process; preparation of analytical notes, test reports, and other case documentation; photography and other imaging; maintenance, calibration, and performance checking of equipment; taphonomic effects and evidence conservation considerations; and, writing and editing Standard Operating Procedures (SOPs).

Quality assurance procedures and programs are ineffective unless they are monitored, enforced, and subjected to corrective action when non-compliances are discovered. Monitoring and corrective actions outline how these are accomplished in the CIL. Discussed are a myriad of surety measures including: proficiency testing; review of court testimony; internal and external audits; annual reports to, and management reviews with, top management; and, corrective action policies and procedures regarding personnel, technical procedures, facilities, etc.

Workshop - 2015

In closing, the workshop discusses problems that hindered, and the processes that led to, the accreditations of the CIL. Surety assistance programs offered by the CIL are discussed in the event an attendee's organization desires assistance with their QAP or accreditation efforts. Additionally, the contributions, to date, of the Scientific Working Group in Forensic Anthropology (SWGANTH) to the human identification profession are briefly discussed.

Quality Assurance, Human Identification, Forensic Anthropology

W18 Sadism: Distinguishing Between Criminal Behavior and Offender Analysis

*Klaus C. Neudecker, MD**, Schirmgasse 268, Landshut, Bavaria D-84028, GERMANY; *Richard D. Walter, MA**, 1879 Chenango Street, Montrose, PA 18801; *Lurena A. Huffman, BS**, 23 N Greenfield Avenue, Hampton, VA 23666; *Amanda L. Farrell, PhD**, Marymount University, School of Education and Human Services, 2807 N Glebe Road, Arlington, VA 22207; and *Patrick Zirpoli**, 149 Spruce Swamp Road, Milanville, PA 18443

After attending this presentation, attendees will have a conceptual and applied understanding of the complexities of sadism (sexual and non-sexual). The framework presented will begin by introducing participants to the history of sadism and reviewing its development as a psychological construct before employing a crime assessment model that utilizes the crime continuum to explicate behavior, not the psychological paradigm currently in use.

This presentation will impact the forensic science community by clarifying the complexities of sadism to facilitate understanding. The attendees will learn the profound impact that sadism has in our daily forensic work in the disciplines of psychology, psychiatry, criminalistics, law, or criminal investigations, as well as in a myriad of hidden inferences in other related disciplines.

Since the invention of the term sadism in the late 19th century and the implementation of the different systems of psychiatric classification, conceptualization of the term and its associated behaviors has been made via a long and circuitous path. This term has been altered and changed to serve various functions and to encapsulate or exclude varying behaviors. The last modification to the term sadism was found in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-V), but still it remains unclear whether sadism is a psychiatric disease (or a so-called “disorder”), a form of sexual deviance, or a criminal behavior. The clarification of this ambiguity would improve forensic-psychiatric classification, diagnosis, and therapy, as well as clarify the difference between the medical approach and the typological and behavioral analyses necessary for crime assessment and crime scene investigations.

After attending this session, attendees should have a conceptual and applied understanding of the complexities of sadism (sexual and non-sexual). The framework presented will begin by introducing participants to the history of sadism and reviewing its development as a psychological construct before employing a crime assessment model that utilizes the crime continuum to explicate behavior, not the psychological paradigm currently in use.

The attendees will learn the evolution of sadism from the original concept development into an abridged form which became applicable only to psychology/psychiatry, where the framework changed to only address the diagnostic and treatment aspects of the behavior and crime. Thus, this abridged viewpoint developed a diagnostic criteria exclusive to the interests of the respective disciplines while ignoring other relevant aspects and disciplines that might contribute to a holistic understanding of sadism. That is, inasmuch as the medical focus was only on diagnosis and treatment, the term became restrictive and devoid of any earlier recognized crime behaviors and patterns. Currently, most clinicians and reference books are caught in a thicket of misapplied understandings that impede correctly and comprehensively evaluating the criminal and/or the crime.

Many clinicians and profilers continue to use the psychological continuum of paraphilias to explain crime, which is founded in the criminological continuum of deviancy. This commingling has led to a quagmire of misunderstanding and bad science.

Predicated upon the original conceptualization of sadism, attendees will learn the intent is the psychological and physical destruction of the victim from ante-mortem, perimortem and post-mortem violence, moving beyond the narrow confines placed upon behavioral analysis in current psychological and psychiatric conceptualizations. Primarily, the focus of the extreme violence is based upon the 3 “D’s,” which are dependence, dread, and degradation. Further, although all sadism does not end in death, the psychopathological direction is toward the ultimate demise and destruction of the victim. As expected, this pathway has a learning curve of behaviors that build upon one another until the extremes are met.

Although many believe that sadism is solely sexual in nature and manifestation, this is inaccurate and a discussion of non-sexual sadism will be advanced and presented in case reports. By removing the limitations earlier imposed by psychiatry and psychology and exploring the behaviors from within the crime continuum, attendees will discover forms of sadism that have been ignored or misunderstood in the past.

This presentation will benefit the forensic science community by clarifying the complexities of sadism to facilitate understanding. The attendees will learn the profound impact that sadism has in our daily forensic work, be it in the disciplines of psychology, psychiatry, criminalistics, law, criminal investigations, as well as in a myriad of hidden inferences in other related disciplines.

Workshop - 2015

The above workshop will be devoted to conceptual and applied cases. Accordingly, there will be some extreme examples that may be overwhelming for some persons.

Sadism, Crime Assessment, Behavior

W19 Automating Image Production for Forensic Document Examiners

Mark Goff, BA*, MSP Lansing Laboratory, 7320 N Canal Road, Lansing, MI 48913; Kevin P. Kulbacki, MSFS, Osborn & Son, 1273 Bound Brook Road, Ste 15, Middlesex, NJ 08846; and F.L. Jim Lee, Jr., MS, PO Box 207, Eden, UT 84310

After attending this presentation, attendees will be able to automate simple tasks and will understand how to combine these simple tasks into complex actions. As an example, attendees will have the ability to take physical evidence consisting of 20 request writing samples on separate forms and create a complete chart of all 20 signatures in approximately five minutes, remove colored backgrounds at the click of a button, or batch-process large quantities of images with a simple drag-and-drop action. The main focus of this presentation will be to demonstrate how the automation of common tasks associated with the production of writing comparison charts, image enhancement, and document-examination demonstrative aids can save time. This is accomplished primarily through the use of Adobe® Photoshop® features, actions, and droplets.

This presentation will impact the forensic society community by explaining that with the increasing documentation requirements for laboratory accreditation, court testimony, and the increasing complexity of cases, the time required for completion of many forensic document examination cases has increased significantly. To help alleviate the additional time requirements, this workshop will include various tips and tricks in Adobe® Photoshop®, Adobe® Acrobat®, and Adobe® Bridge® to reduce the amount of time the examiner spends preparing and organizing documentary evidence prior to the actual examination.

This workshop is designed specifically for forensic document examiners. Software in common use among forensic document examiners will be demonstrated and shown how it can be used to increase productivity. This is accomplished without any knowledge of computer programming or the requirement to write scripts, but through the process streamlining image production and the automation of common tasks in Adobe® Photoshop®.

Creating writing charts has historically involved the physical cutting and pasting of signatures or words used for comparison onto a backing. This has been a very time and labor intensive process that progressed from using photography, to photo copiers, and finally digital imaging. Unfortunately many document examiners still construct writing charts in a similar manner to the way they were constructed a hundred years ago, by digitally cutting and pasting the individual writings onto a blank back ground. While searching for a way to streamline examination processes, automating repetitive tasks for these digital charts greatly reduced the amount of time spent on cases overall. In many instances it was found that the creation and use of appropriate actions in Adobe® Photoshop® can save a significant amount of time. The time spent constructing printed charts from physical writing exemplars can be reduced from an hour or more to less than five minutes at times.

The first part of the workshop will outline types of computer hardware and peripherals that can be used to accelerate the task of image production. This will include recommendations on how to configure scanners and computer workstations to achieve maximum productivity with minimal user input. The instruction will not be an endorsement of specific items but more of a description of the tools necessary to reduce time spent on imaging documentary evidence. When large numbers of images are created, managing these images then becomes a time consuming task. Quick and easy methods for the naming, searching, and categorizing of these images after creation will also be demonstrated.

The main focus of this workshop will be to demonstrate how the automation of common tasks associated with the production of writing comparison charts, image enhancement and document examination demonstrative aides, can save the attendee time. This is accomplished primarily through the use of Adobe® Photoshop® features, Actions, and Droplets. Upon completion of this workshop, the attendee will have a basic understanding of the features within Adobe® Photoshop® that can be used to execute repetitive tasks at the press of a button.

With the knowledge gained at this workshop the attendee will be able to automate simple tasks and will know how to combine these simple tasks into complex actions. As an example, the attendee will have the ability to take physical evidence consisting of 20 request writing samples on separate forms and create a complete chart of all 20 signatures in about five minutes, remove colored backgrounds at the click of a button, or batch process large amounts of images with a simple drag and drop action. This workshop is paced to maximize the amount of time spent working with hands on examples to ensure these techniques can be used when the attendee gets back to the laboratory. Graphic step-by-step instructions will be provided for future reference.

Documents, Photoshop®, Imaging

W20 Cognitive Bias Issues in the Forensic Analysis of Pattern and Impression Evidence and in Medicolegal Evaluations

*Andrew Sulner, MSFS, JD**, Forensic Document Examinations, LLC, 220 E 57th Street, Ste 200, New York, NY 10022; *Barry C. Scheck, JD**, The Innocence Project, 40 Worth Street, Ste 701, New York, NY 10013; *Keith A Findley, JD**, University of Wisconsin Law School, 975 Bascom Mall, Madison, WI 53706; *Saul Kassin, PhD**, John Jay College of Criminal Justice, 524 W 59th Street, New York, NY 10019; *Glenn M. Langenburg, PhD**, 1430 Maryland Avenue, E, Saint Paul, MN 55106; *Daniel A. Martell, PhD**, Park Dietz & Associates, 2906 Lafayette, Newport Beach, CA 92663; *Daniel C. Murrie, PhD**, 1330 Amber Ridge Road, Charlottesville, VA 22901; *Michael Risinger, JD**, One Newark Center, Newark, NJ; *Donald E. Shelton, JD, PhD**, 500 S Harris Street, Saline, MI 48176; *Dan S. Simon**, Los Angeles, CA 90089; *William C. Thompson, PhD, JD**, University of California, Dept of Criminology, Law & Society, Irvine, CA 92697; *Deborah Tuerkheimer, JD**, Northwestern University School of Law, 357 E Chicago Avenue, Chicago, IL 60601; and *Lucy B. Rorke-Adams**, The Children's Hospital of Philadelphia, Department of Pathology, Philadelphia, PA 19104

After attending this presentation, the attendees will be acquainted with the different types of bias that can influence the outcome of forensic investigations. Attendees will learn about classic psychological research studies and real-life case histories demonstrating the effects of bias upon interpretations of pattern and impression evidence and upon medicolegal evaluations and assessments, especially in Shaken Baby Syndrome/Abusive Head Trauma (SBS/AHT) cases. Attendees will also discover how bias can improperly sway the perceptual and cognitive judgments of forensic examiners and produce faulty conclusions, even in the absence of malicious intent.

This presentation will impact the forensic science community by clearly demonstrating how various types of bias can adversely impact evaluations of evidence and decision-making in all forensic disciplines. Understanding the sources of bias and learning how to limit or minimize their influence is essential for improving the reliability and accuracy of decisions made by forensic experts and avoiding miscarriages of criminal and civil justice. All forensic scientists and laboratory directors must be keenly aware of the potential for bias and the types of internal procedures and protocols that can and should be implemented to minimize the impact of bias in forensic investigations and casework.

An extensive body of experimental research conducted by cognitive and social psychologists, as well as empirical data obtained from recent research and forensic casework studies, clearly demonstrates that various sources of bias can and often do adversely impact a forensic examiner's visual perception and decision making. Perceptual and cognitive judgments made by forensic examiners performing comparative analyses of fingerprints, hair, tool marks, bite marks, handwriting, and even DNA typing are susceptible to biasing influences that can improperly taint and sway the examiner's decision making process, as are other types of forensic evaluations, such as medical assessments made by physicians or health care providers as to whether a physical injury or death was accidental or willful. Understanding these various sources of bias and learning how to limit or minimize their influence is essential for improving the reliability and accuracy of decisions made by forensic and medical experts. The other participants in the administration of criminal and civil justice — lawyers and judges — likewise need to fully appreciate and comprehend the negative impact that biasing influences may have on the outcome of a forensic or medical expert's analysis of evidence. In our adversarial judicial system, trial lawyers need this knowledge in order to effectively expose potential biasing influences when cross-examining an opposing forensic or medical expert, and judges need it to be more mindful of the critical role that bias plays in producing miscarriages of criminal and civil justice. All stakeholders in the administration of criminal and civil justice must be keenly aware of the potential for bias and the types of internal procedures and protocols that can and should be implemented to minimize the impact of bias in forensic investigations and casework.

In this workshop, a multidisciplinary faculty of distinguished psychologists, lawyers, forensic scientists, and others will provide attendees with a clear picture and concrete examples of how and why bias affects the outcome of forensic investigations. Attendees will learn about the various experimental research studies that reveal the susceptibility of investigations to the prospect of psychological error due to cognitive and motivational factors, including confirmatory biases, dynamic influences, group membership, role conflict, escalation of commitment, and adversarial allegiance. The unique persuasive power of confessions — even false confessions that are recanted and contradicted by other evidence — will be discussed in the context of basic and forensic psychology research which indicates that confessions influence lay witnesses and forensic science examiners across a range of domains, thereby increasing the risk of wrongful convictions.

Workshop - 2015

Attendees will learn about practices that should be avoided and followed in order to minimize potential biasing influences. Examples from actual forensic casework in both criminal and civil cases will be used to illustrate the impact of bias on the outcome of forensic examinations and the manner in which such opinions are expressed in court. Interesting data obtained from recent research studying the problem of contextual bias as encountered in national security investigations conducted by laboratory scientists working in the area of chemical, nuclear/radiological and biological Weapons of Mass Destruction (WMD) forensics will also be discussed, along with steps that these scientists have taken to address this problem.

How lawyers might seek to exclude proffered expert opinion infected by the precursors of bias and to impeach expert testimony that may have been tainted by bias will also be discussed. Gatekeeper decisions about admissibility, the use of cautionary jury instructions when serious issues of cognitive bias have been raised during the trial, and whether to allow expert testimony from a qualified psychologist about the effect of cognitive bias on judgments made by forensic experts will be addressed.

Due to the fierce controversy that has developed within the medical and legal communities surrounding the diagnosis of Shaken Baby Syndrome (SBS), a.k.a Abusive Head Trauma (AHT), attendees will also learn about the various cognitive biases that can affect clinical observations and evaluations upon which decisions are based as to whether infant brain injuries should be attributed to abuse or accident. Distinguished faculty members will discuss: the triad of symptoms historically relied upon to diagnose SBS/AHT; the cognitive bias issues presented in the absence or presence of additional signs of possible abuse; the impact that confessions and other domain-irrelevant information may have upon the outcome of medical evaluations and diagnoses of SBS/AH; and, the need to consider alternative hypotheses or explanations, such as diseases or conditions that can mimic the symptoms typically associated with SBS/AHT.

Finally, the presentations will be followed by a Q&A session in which panel members will be able to provide additional information to inquiring attendees.

Cognitive Bias, Flawed Forensics, Shaken Baby Syndrome

W21 Death in a Bathtub: The Trial of Drew Peterson

*Mary E.S. Case, MD**, 6059 N Hanley Road, St. Louis, MO 63134; *James Glasgow, JD**, Will County Illinois States Attorney, 121 N Chicago Street, Joliet, IL 60432; *Jeffrey M. Jentzen, MD**, University of Michigan, 300 N Ingalls, NI2D19 - SPC 5452, Ann Arbor, MI 48109; and *Andrea Zaferes, BA**, PO Box 594, Shokan, NY 12481

After attending this presentation, attendees will understand the courtroom procedures for admission of evidence and expert witness testimony. In addition, attendees will learn the factors involved in injury identification and analysis with an emphasis on the investigation of drowning.

This presentation will impact the forensic science community by presenting the multidisciplinary reconstruction of one of the most riveting cases in recent American trial history. This presentation will detail the factors and evidence that influenced the decision-making process and will assist future prosecutors, judges, and death investigators in courtroom procedures.

In 2004, the body Kathleen Savio, the third wife of policeman Drew Peterson was found dead in the bathroom of her suburban Chicago home. Her body was found lying in an empty bathtub with a small laceration to the left back of the scalp. Froth oozed from her nostrils. There were some bruises to her left side. Toxicology analysis was negative for intoxicating drugs and alcohol. The initial investigation concluded that the death was the result of drowning and the coroner certified the death accidental. In 2007, Peterson's fourth wife, Stacey Peterson disappeared — her body never recovered. In light of Stacey Peterson's disappearance, authorities reopened the investigation into Savio's death.

Savio's body was disinterred in 2007 and reexamined in two separate autopsies performed by a group of forensic pathologists. The pathologist identified areas of hemorrhage over the left hip region, not appreciated at the initial examination. In light of the additional evidence, the experts concluded that Savio's death was a homicide.

In criminal cases, there is a constitutional dimension to hearsay. The Sixth Amendment gives criminal defendants the right to confront witnesses; since a hearsay statement is made out of court, there is no opportunity for the defendant's criminal defense attorney to cross examine the witness, and thus no confrontation. This means hearsay statements are harder to get into evidence even via the traditional hearsay exceptions when they are used against a criminal defendant.

Prosecutors collecting evidence identified the fact that Stacey Peterson had confided with family and friends implicating her husband, Drew Peterson as her murderer. Unable to question the dead witness, prosecutors petitioned the Illinois legislature to create a new exemption to the hearsay rule, which became known as "Drew's Law." The law allowed for the admission of evidence in cases where the witness was not available to testify due to the actions of the defendant. Meanwhile, defense experts unsuccessfully attempted to exclude testimony related to Stacy Peterson's disappearance in a 2010 evidentiary trial.

The trial of Kathleen Savio's death began in August of 2012. For over six weeks of grueling testimony, the media provided the day-to-day revelations of the case. Five forensic pathologists testified in the case that called into question central to the cause and manner of death. All the pathologists agreed that Savio died of drowning. The pathology testimony rested on questions of the pathological findings of concussion, postmortem artifacts, orientation of injuries, and causes of accidental drowning.

In light of new legislation, the prosecution was allowed to present incriminating verbal testimony against Drew Peterson. Peterson was eventually convicted, sentenced to 38 years in prison for his role in death of Kathleen Savio. The jurors said that the most convincing testimony was hearsay statements allowed into evidence under a new law, known as "Drew's Law," named after Peterson. Prosecutors successfully fought to have statements made by Stacy Peterson and Savio to acquaintances admitted into evidence. In February 2013, the defense was denied a new trial. The trial left numerous questions unanswered and created a precedent of allowing indefensible hearsay testimony

This workshop will be presented by the pathologists, prosecutors, and expert witnesses actually involved in the case. It will provide a multidisciplinary approach to courtroom presentation of evidence, expert testimony, the role of the medical witness and criminalistics evaluation, and the physiology of drowning. Participation of attendees is encouraged and will bring to life the tension of the courtroom in this precedent-setting prosecution.

Drew Peterson, Drew's Law, Bathtub Drowning

W22 Looking Toward a Greater Awareness of Youth Street Gangs

Cliff Akiyama, MPH, MA, Akiyama and Associates, LLC, 540B S 48th Street, Philadelphia, PA 19143; and Janet B. Duval, MSN*, 9383 E County Road, 500 S, Greensburg, IN 47240-8138*

After attending this presentation, attendees will be able to: (1) explain the organization and historical evolution of youth street gangs (examining African American, Latino, Asian, and Caucasian youth street gang activities from the crimes they commit to their tattoos, graffiti, and hand signs); (2) distinguish the behavioral differences and similarities between gangs (evaluating why one decides to join a gang and the motivational factors that play a role in gang membership); (3) compare and contrast activities of various gangs; and, (4) explore the issue of female gang members and sexual assault.

This presentation will impact the forensic science community by increasing understanding of the crimes and circumstances that involve youth street gangs.

Youth gang violence has continued its upward trend nationwide. It was once thought that gangs only convened in selected areas, which left churches, schools, and hospitals as “neutral” territory. Unfortunately, this is a fallacy. Gang violence has poured into the schools, community centers, and hospitals. Not only in California is gang violence problematic, as often the media portrays, but also throughout the United States gang violence has risen over 35% in the last year. Youth gang violence continues to rise dramatically with more and more of our youth deciding to join gangs each and every day. Sadly, every single state has gangs and the problem is getting much worse in areas that would never have thought about gangs a year ago. These “new generation” of gang members are younger, much more violent, and staying in the gang longer. Gangs are not just an urban problem, but a suburban and rural problem too. There are over 25,500 gangs in the United States with a total gang membership of 760,000 (94% are male and 6% are female). The ethnic composition nationwide include: 47% Latino, 31% African-American, 13% Caucasian, 7% Asian, and 2% “mixed,” according to the Office of Juvenile Justice and Delinquency Prevention of the Department of Justice.

A youth gang, often referred to as a “criminal street gang” by law enforcement must be ongoing, meaning that the gang associates on a continuous or regular basis. The youth gang could be formal or informal. Moreover, the youth gang must consist of at least three members and have a name, hand sign or symbol which is identifiable. The final element that defines a youth gang is that one of the primary objectives of the gang must be criminal activity. Not to get confused with various social groups such as fraternities, sororities, or social clubs, what differentiates a youth gang from other groups is its criminal activity.

In all of the 25,500 youth gangs with over 760,000 gang members across the nation, there are various types of gang members ranging from hardcore to wannabe members. The most plentiful type of gang member is the active/regular gang member making up between 40-50% of the gang. Regular gang members self-admit that they are in a gang when asked. They also have gang related tattoos, involved in gang related crimes, and have a past history of gang activity. Associate/affiliate gang members make up 20-30% of the gang. Associate and regular gang members also use hand signs to communicate to each other and to other rival gangs. Associate and regular gang members also write gang graffiti, wear gang related clothing (colors), associate with known gang members, and are included in gang photos. What sets associates apart from regular members is that they are able to freely come and go in and out of the gang as they see fit making them great informants for law enforcement. The hardcore gang members known, as an Original Gangster (OG), make up 10-20% of the gang and is the primary leadership arm of the gang group. Furthermore, hardcore gang members are involved in violent gang activity from assaults, shootings, robberies, to murder. Wannabes are the last group of gang member types. Wannabes make up less than 10% of the gang however are extremely dangerous. Not to say that the other gang member types are not dangerous because they all have the potential to be extremely dangerous. The dangerousness of the wannabes lies in their motivation to be part of the gang.

As a result of the ongoing proliferation of youth street gangs in our communities, it is imperative that medicolegal death investigators, forensic nurses, law enforcement, district attorneys, coroners, medical examiners, social workers, educators, and others involved with the direct care become educated on how to identify gang members, their activities, and their motivations so that they could provide solutions to families and the youth themselves to help eradicate the problem of gang violence, while keeping safe.

Youth Gangs, Youth Violence, Violence Prevention

W23 Hands-On Evaluation of the Thanatomicrobiome and Epinecrotic Communities

*Gulnaz T. Javan, PhD**, Alabama State University, Forensic Science Program, 915 S Jackson Street, Montgomery, AL 36104; *M. Eric Benbow, PhD**, Michigan State University, Dept of Entomology & Medical Specialties, 288 Farm Lane, East Lansing, MI 48824; *Daniel J. Wescott, PhD**, Texas State University, Dept of Anthropology, 601 University Drive, San Marcos, TX 78666-4684; *Sharon L. Plotkin, MS**, Miami Dade College, 11380 NW 32 Avenue, Miami, FL 33167; *Sheree J. Finley, MS**, Alabama State University, 915 S Jackson Street, Montgomery, AL 36104; *Jennifer L. Pechal, PhD**, Michigan State University, 243 Natural Science Bldg, 288 Farm Lane Road, East Lansing, MI 48824; and *Ismail Can**, 915 S Jackson Street, Montgomery, AL

After attending this presentation, attendees will be able to: (1) describe the process by which crime scene investigators approach human remains for the collection of microbial and entomological evidence; (2) collect genomic DNA evidence from human cadaver-associated soil using readily available DNA extraction kits to isolate and assess the quality of genomic DNA to be used in downstream molecular applications; (3) describe and critically evaluate the benefits and challenges of the thanatomicrobiome and epinecrotic communities for use in forensic research and potential use during investigations for estimating the Postmortem Interval (PMI); (4) discuss the bioinformatics of specific sequencing platforms and the use of multivariate statistical procedures and modeling that are increasingly being used in metagenomic analyses or postmortem microbial communities; and, (5) understand and appreciate the benefits of outdoor decomposition facilities for more realistic studies of postmortem microbial communities.

Additionally, attendees will participate in a hands-on experience learning techniques to extract DNA from: soil samples, eggs, larvae, pupae, and adult insects.

This presentation will impact the forensic science community by providing an introduction to the principles behind the potential use of postmortem microbial communities in death scene investigations and the methods to use in extracting microbial DNA from a variety of sources. Emphasis will be placed on introducing new forensic scientists to practical aspects of DNA extraction techniques and the use of thanatomicrobiome and epinecrotic communities in the estimation of the PMI.

Accurate estimation of Postmortem Interval (PMI) is a major challenge for forensic examiners. Advances in DNA sequencing technology have created new possibilities and approaches to PMI estimation. Use of these techniques has generated new areas of research for scientists. This presentation is intended to provide attendees with an introduction to this emerging approach to PMI estimation.

Upon completion of the morning session of this workshop, the participants should be able to: (1) describe the process by which crime scene investigators approach human remains for the collection of microbial and entomological evidence; (2) collect genomic DNA evidence from soil using readily available DNA extraction kits to isolate and assess the quality of genomic DNA to be used in downstream molecular applications; (3) describe and critically evaluate the benefits and challenges of the thanatomicrobiome and epinecrotic communities for use in forensic research and potential use during investigations for estimating the PMI; (4) discuss the bioinformatics of specific sequencing platforms and the use of multivariate statistical procedures and modeling that are increasingly being used in metagenomic analyses or postmortem microbial communities; and, (5) understand and appreciate the benefits of outdoor decomposition facilities for more realistic studies of postmortem microbial communities.

Thanatomicrobiome, Epinecrotic Communities, DNA Extraction

W24 Scientific Neutrality in Expert Witness Testimony

*Charlotte J. Word, PhD**, PO Box 5207, Gaithersburg, MD 20882; *Christopher J. Plourd, JD**, *Christopher J. Plourd, JD*; Superior Court; 939 Main Street; El Centro, CA 92243; *Lewis H. Buzzell, JD**, Private Criminal Defense Attorney, 9443 Crystal Springs Road, Jacksonville, FL 32221; *Ronald Reinstein, JD**, AZ Supreme Court, 1501 W Washington, Ste 344, Phoenix, AZ 85007; and *Tammy Spurgeon, JD**, 401 Civic Center Drive, W, Santa Ana, CA 92701

After attending this presentation, attendees will better understand: (1) how to achieve neutrality in the preparation for and presentation of both direct and cross-examination in court; (2) how to testify within the limits of his/her expertise; (3) the role and responsibilities of the expert witness in and out of the courtroom and how the expert testimony relates to the roles and responsibilities of the judge and the prosecuting and defense attorneys; and, (4) the importance of being a neutral expert witness.

This presentation will impact the forensic science community by elucidating the importance and value to our justice system of an expert witness who maintains neutrality during expert witness testimony in depositions and in the courtroom. This presentation will provide all current and future expert witnesses in all areas of forensic sciences an opportunity to learn from an experienced expert witness and other knowledgeable members of the courtroom, including a judge, a defense attorney, and a prosecuting attorney.

Each participant in the court room and in the justice system has a specific advocacy role to ensure that justice is properly and appropriately administered. The very nature of the trial advocacy system often places the forensic scientist in what could be perceived as an advocacy role for the prosecution or the defense; however, judges, and prosecuting and defense attorneys should have the same objectives regarding scientific expert witness testimony in that the witness must be truthful, forthcoming, and as neutral as possible.

The respective roles of the judge, the attorneys and the forensic science expert witness in the courtroom and how the roles impact the testimony of the expert witness will be discussed from the perspective of an experienced prosecuting attorney, defense attorney, judge, and expert witness. Attendees will be provided valuable tools for effective presentation of scientific evidence while maintaining scientific neutrality during court testimony, including during direct and cross-examination, as well as throughout the testing process and reporting in order to be true to the science and to the results obtained. A portion of the session will be devoted to a panel discussion where relevant issues and questions from the panel and the audience will be addressed by each of the speakers who will give practical advice and demonstrate applications of the information provided. Examples of questions to be covered are: "What should I do if I am asked by an attorney to give opinions that are contrary to my conclusions and opinions?" and "How do I handle questions regarding mistakes, errors, and other issues in the laboratory?" Attendees are encouraged to bring tough real-life questions for the speakers to address and witness how much agreement there is between all participants in the courtroom when the goal is factual, truthful and neutral testimony. It is important for all forensic science expert witnesses to recognize and understand for all future testimonies that their only advocacy role is for good science and the truth through competent and unbiased testing and testimony.

Attendees may be inclined to believe that they play the role of an advocate since they are called by either the prosecution or defense; however, it is the forensic scientist's role to ensure that expert testimony is factual, truthful, and unbiased. Valuable tools for effective presentation of scientific evidence while maintaining neutrality will be provided from the perspective of an experienced prosecuting attorney, defense attorney, judge, and expert witness. The respective roles of the judge, the attorneys, and the forensic science expert witness in the courtroom and how the roles impact the testimony of the expert witness will be discussed. Relevant issues and questions will be discussed with practical advice and applications of the information provided.

Neutrality, Expert Witness, TestimonyA Title Sample

Anthropology Section - 2015

A1 Temporal Patterns of Mexican Migrant Ancestry: Implications for Identification

*Cris E. Hughes, PhD**, Department of Anthropology, 109 Davenport Hall, 607 S Matthews Avenue, Urbana, IL 61801; *Bridget F.B. Algee-Hewitt, PhD*, Stanford University, Rosenberg Lab, Dept of Biology, Gilbert Bldg, Rm 109, 371 Serra Mall, Stanford, CA 94305-5020; *Elizabeth S. Clausing*, University of Illinois at Urbana-Champaign, 307 E White Street, Apt 25, Champaign, IL 61820; and *Bruce E. Anderson, PhD*, Pima County OME, Forensic Science Center, 2825 E District Street, Tucson, AZ 85714

After attending this presentation, attendees will learn how genetic ancestry estimates can be used to reveal the dynamics of demographic trends in United States-Mexico border casework, thus contributing to the continuous refinement of identification logistics.

This presentation will impact the forensic science community by validating that the science of producing evidence alone is not enough to maintain identification rates in complex identification contexts like the border dead. The ongoing efforts of culturally conscious caseworkers and outreach groups, who explain the identification process, collect family reference samples, and source antemortem data is essential for the continued success of identifications at medical examiners' offices. This interdisciplinary approach to identifications could be used in other investigative contexts as well.

As understanding the geo-temporal patterns of who is dying on the border and who is being positively identified speaks to casework logistics, attendees will see how studying the ongoing evolution in Undocumented Border Crossers (UBC) demographics provides insight for modifying current identification protocols.

The United States-Mexico border remains a key focal point for developing new approaches to the identification of migrant remains, as the rates of cross-border fatalities continue to rise and source populations continue to diversify. As demonstrated by the Pima County Office of the Medical Examiner (PCOME), the identification of border remains is an interdisciplinary effort, requiring skillful integration of multiple lines of biological and social information. The present study focuses on how genetic ancestry estimates from standard forensic DNA markers in UBC cases provide valuable insight into border crossing deaths and identification patterns over time, and how this information has practical implications for future identification rates in forensic anthropology as the population make-up of undocumented migrants continues to change.

Genetic ancestry estimates were generated using Combined DNA Index System Short Tandem Repeat (CODIS STR) loci for both identified (n=97) and unidentified UBC cases (n=262) recorded by the PCOME from 1972 to 2013. These estimates were generated in STRUCTURE software, under a k=2 model, using European and Native Mexican reference samples. To identify temporal trends in the genetic ancestry of the UBC cases, ancestry proportions for the identified and unidentified UBC samples were tested separately for a significant correlation with case year. A positive correlation ($r=0.27$, $p<0.0001$) between case year and Native American ancestry for unidentified UBC cases was found. Compared to Mestizos, indigenous populations on average exhibit greater amounts of Native American ancestry; thus, these temporal trends are consistent with current reports of an increased rate of migrants from southern Mexico, where the largest concentration of indigenous populations reside. In contrast, a negative correlation with Native American ancestry and a positive correlation with European ancestry was found for the positively or presumptively identified UBC cases, with values approaching statistical significance ($r=-0.16$, $p=0.105$). Skeletal data offer external support, as neurocranial Interlandmark Linear Distances (ILD) variables for identified cases also show a negative correlation with Native American ancestry (n=83, $r=-0.20$, $p=0.0473$).

These contrasting trends suggest an identification bias, implying that the success of identifications will decrease over time as the prevalence of UBC cases with increased Native American ancestry grows. PCOME-reported identification rates have decreased from 75% in 2003 to 45% in 2013, and although identification success is attributable to many factors, this trend in decreasing rates supports the genetic ancestry-based findings reported here. Given these results, it is critical to isolate the factor(s) driving this identification bias. It is unlikely that identification bias is produced at the case-evidence level, because all cases investigated at PCOME undergo similar protocols for skeletal and DNA analyses. One possible explanation may be the lack of family reference DNA samples from more rural, southern, and indigenous communities. Families of missing or deceased migrants from these backgrounds may be less accessible to Non-Governmental Organizations (NGOs). If these families are not reached, or are less inclined to provide DNA samples, identification potential drops significantly.

Anthropology Section - 2015

This study analysis demonstrates how forensic investigations should place greater emphasis on and receive increased support for the community outreach work lead by national and international NGOs. These results validate that the science of producing evidence alone is not enough to maintain identification rates, as the demographics of UBCs change over time. The ongoing efforts of culturally conscious caseworkers and outreach groups, who explain the identification process, collect family reference samples, and source antemortem data, is essential for the continued success of identifications at medical examiner offices. Since the 1990s, PCOME has led the development of flexible and innovative approaches to identification that meet the complex challenges of UBC casework. As UBC demographics are in a state of flux, in order to continue to improve identification rates, forensic approaches must be adaptive and balanced with a focus on both the forensic science and the social science of identification.

Mexican Migrant, CODIS STR, Ancestry

A2 “I Learned About My Death From the Newspapers” — Misidentification Following Cutbacks After a Spending Review

Ilaria De Vitis, Via Carducci 23, Cavallino (le) 73020, ITALY; Liliana Innamorato, MD, D.I.M, sezione di Medicina Legale, piazza Giulio Cesare, 11, Bari 70124, ITALY; Vittoria Del Vecchio, MD, Section of Legal Medicine D.I.M., piazza Giulio Cesare, 11, Bari 70124, ITALY; Leonardo Traversa, MD, University of Bari, Section of Legal Medicine, Bari 70124, ITALY; Valentina Ronco, MD, Section of Legal Medicine D.I.M., piazza Giulio Cesare, 11, Bari 70124, ITALY; Valeria Viterbo, MD, Section of Legal Medicine D.I.M., piazza Giulio Cesare, 11, Bari 70124, ITALY; and Francesco Introna, MD, Dim Sezione Di Medicina Legale, P.zza Giulio Cesare 11, Bari 70124, ITALY*

After attending this presentation, attendees will understand that it is essential, even in a period of financial crisis and cutbacks after a spending review, to perform all the investigations on an unknown corpse.

This presentation will impact the forensic science community by demonstrating the fundamental need to perform proper identification procedures. Failure to perform such procedures, deemed unnecessary and costly, could result in declaring the death of a living subject and the burial of a corpse under a false name.

In December 2013, firemen were called to a fire in an abandoned farmhouse in a rural area near Binetto, a small town in the province of Bari (Apulia, Italy). While dousing the flames, the firemen found an extensively burned corpse. The body was lying near a fireplace, in the “boxer’s” position. The skull was skeletonized and extensively charred. The limbs were amputated and charred from the heat. The thoracic and abdominal cavities were exposed and the internal organs were blackened and shrunken. The sex was identified, but transformational phenomena due to the heat and flames did not allow the age and height to be determined. At the end of the preliminary survey, it was not possible to determine the cause or the time of death, nor to make a clear identification of the corpse.

From the statements issued by the owner of the farmhouse as well as by the inhabitants of the small town, it was learned that “R.R.,” a homeless immigrant with a valid residence permit, frequently took shelter in the farmhouse. Therefore, the police and the state prosecutor decided to identify the cadaver as that of R.R., and it was considered unnecessary, in view of stringent cutbacks, to proceed with an autopsy or further investigations to ascertain the identity and the cause of death of the burned corpse and the case was closed. Two days after the identification of the corpse, R.R. arrived at the police station stating that he had learned, to his surprise, the news of his own death from the newspapers. He reported that the house was used as a shelter by various immigrants.

In this case, a misidentification of a body had occurred due to economic problems and the general dispositions of the spending review. At this point, the question was: who was the charred body?

The police compiled identity photographs of missing immigrants. Due to the flame-damaged, charred soft tissues of the face, it was not possible to visually identify the corpse, nor was it possible to carry out DNA analysis because of the lack of close relatives for comparison. Antemortem medical files were not available. The only feasible identification procedure was a parameterized skull-photo superimposition of the face using a 3D Computed Tomography (CT) scan. This technique involves superimposing a computed, parameterized 3D facial image over photo images considered a possible match with the remains. During the autopsy, the charred skull was carefully removed and subjected to adequate preservation treatment for the subsequent identification investigations.

The 3D reconstruction of the skull was carried out by employing an open 3D Cone Beam CT (CBCT) acquisition system, normally used for facial mass studies. The 3D image of the skull, according to precise dimensional anthropometric constraints, was mobilized by software and superimposed on photographs of the faces of missing immigrants. At the end of the survey, there was evidence of a perfect parameterized overlap of the skull with the photo of another immigrant, H.A. Notably, the victim was physically quite unlike R.R., who had previously erroneously been identified as the corpse under examination by the state attorney and the police.

Charred Body, Identification, 3D CT Scan

A3 The Relevance of a Multidisciplinary Approach in the Identification of Skeletal Remains: A Case Report

Monica Pedretti, MD, via Roma 55, Pisa 56100, ITALY; Stefania Fornaro, MD, Via Roma 55, Pisa 56100, ITALY; Laura Roas, MD, via Roma 55, Pisa 56100, ITALY; Valentina Bugelli, MD, Institute of Legal Medicine, via Roma 55, Pisa 56126, ITALY; Isabella Spinetti, PhD, University of Pisa, via Roma, Pisa 56100, ITALY; Claudia Giaconi, MD, University of Pisa, via Roma, 55, Pisa 56100, ITALY; Davide Caramella, MD, University of Pisa, via Roma, 55, Pisa 56100, ITALY; Simona Minozzi, University of Pisa, via Roma, 57, Pisa 56100, ITALY; Marco Caccianiga, PhD, Via Celoria, 26, Milan 20133, ITALY; Luigi Papi, University of Pisa, Institute of Legal Medicine, Via Roma 67, Pisa 56100, ITALY; and Ranieri Domenici, MD, University of Pisa, via Roma, Pisa 56100, ITALY*

The goal of this presentation is to introduce attendees to a multidisciplinary approach to the identification of human remains findings. Specifically, the presentation will focus on the enrichment of any aspect of information on any given case regarding time-since-death occurrence, records related to the involved subject, and, whenever available, information useful for the identification of the subject.

This presentation will impact the forensic science community by highlighting the relevance of a multidisciplinary approach to the management of cases of skeletal remains retrieval.

This study will address two major areas: (1) who the person was; and, (2) how long the remains were lying in the place where they were found. The rationale and background for this approach is based on the following assumptions: (1) postmortem interval estimations are generally based on the degree of soft tissue decomposition, identifiable stages of tissue alteration and loss that occurs in a predictable, sequential, and semi-continuous pattern at a rate that is dependent on both accumulated temperature over time (measured in Accumulated Degree Days (ADD)) and insect access; and, (2) the age of the subject could be estimated by looking at the stages of union for the epiphyses in the different bones and comparing this to the standard growth tables.

Case Presentation: An advanced decomposed leg was found in a field bordering the Arno River in Tuscany, Italy, after a flood had recently occurred. The findings consisted on a foreleg wearing a tennis shoe and included a tibia, a fibula with no soft tissue, and a femur with partial muscle flesh attached. Within seven meters of the leg, a soft tissue mass weighing about ten grams was also found. Every portion of the soft tissue was already saponified and the remains were overgrown with vegetation and mud.

Believing that diverse information gathered from different forensic approaches should assist in shedding light on any given case, it was thought that the victim was likely a young male between 18 and 25 years old. The case could not rely on DNA test matching or comparisons with any other samples collected for identification as none of these samples matched the description of a comparable male subject missing in that area within a reasonable period of time. Remarkably, botanical investigation highlighted the presence of different types of seeds related to a specimen distinctive to areas of fresh water which actually matched the place where the remains were retrieved, providing evidence suggesting they were found in that place before late winter. Also, a complete radiological investigation, including Computed Tomography (CT) and X-rays failed to show any evidence of degenerative articular disease or previous fractures. The X-ray of the femur epiphysis revealed a complete stage of union for the epiphyses, so it was possible to establish the above-mentioned age interval. The anthropological investigation enhanced the identification process. In fact, following a one-month stay in a fresh-water environment, the bones were clean and free of soft issue, which readily allowed the anthropological study. Additionally, measurement of the size of the skeletal remains suggested the age range of the subject and his lifestyle contributed to gender identification. The remains were estimated to be of a male subject with an average Body Mass Index (BMI), around 174cm tall, possibly involved in some physical activity such as squatting. Finally, the DNA analysis confirmed the gender of the subject as male although no confirmatory analysis based on samples collected from other suspect victims could be gathered so a firm conclusion on the actual identity of the subject remains unknown.

In conclusion, despite the inability to perform a DNA matching test, this study demonstrates the relevance of a multidisciplinary approach which significantly helped in gathering a variety of information for preliminary identification of the subject.

Remains, Multidisciplinary Approach, Forensic Anthropology

A4 Estimation of Age From the Adult Pelvis: A Comparison Across Different Pelvic Sites and Statistical Methods

Molly Miranker, BA*, 1078 Fulton Street, #5G, Brooklyn, NY 11218

After attending this presentation, attendees will understand how reliable the estimated age is from three separate pelvic sites compared to one another and why the statistical methods employed in these aging techniques influences the estimates' reliability.

This presentation will impact the forensic science community by demonstrating which of the pelvic aging methods is most reliable and what future research is necessary to improve age estimation for constructing a biological profile.

Age estimation from skeletal remains is a crucial component for generating a biological profile, the use of which assists in the identification of an individual. Bony changes at three pelvic sites (the pubic symphysis, auricular surface, and acetabulum) have been shown to correlate with aging. There have been multiple studies testing the reliability of the pubic symphysis and the auricular surface and comparing those two sites, but few assess the acetabulum and none compare the reliability across all three sites.

Four aging methods were compared in this study: (1) the Suchey-Brooks pubic symphysis method; (2) the Osborne et al. auricular surface method; (3) the Rissech et al. method for the acetabulum; and, (4) the Calce method for the acetabulum.¹⁻⁴ The Suchey-Brooks method was selected because it is one of the most frequently used in biological profiling. The Osborne et al. method was used because it provides more discrete age ranges than other auricular methods. Two acetabular methods (Rissech and Calce) were applied because age estimation techniques have recently been developed for this region and all require additional testing.

A total of 212 known-age individuals housed at the Bass Donated Skeletal Collection were examined. The sample was comprised of individuals of European ancestry who died in the United States during the mid- to late-20th century. The study sample ranged from 26 to 95 years of age, with a mean age-at-death of 62 years. Although the sample was selected to be representative across the decades of life, the age distribution was not normal (Shapiro-Wilk W test $p=0.013$, Skew=-0.203).

The reliability of the four methods was assessed by comparing the accuracy (percentage of point age estimates that fall into the predicted age range of a method), inaccuracy (average absolute difference between known and estimated ages), and bias (amount age is over- or underestimated) of the age estimates produced by each method. These data demonstrate which method(s) were most reliable, in what contexts, and therefore, most useful for describing skeletal remains.

In terms of accuracy, the acetabular aging methods represented the most and least accurate of the techniques (96% Rissech and 59% Calce). The Osborne et al. method had 86% accuracy and Suchey-Brooks 64% accuracy. The Rissech et al. method had the smallest margin of inaccuracy (± 9 years), followed by Calce (± 13 years), Osborne et al. (± 16 years), and then Suchey-Brooks (± 19 years). Bias tests revealed the tendency for all the methods to underage individuals. The Rissech et al. method only slightly underestimated age (-0.70 years), followed by Calce (-5 years), Osborne et al. (-14 years), and finally Suchey-Brooks (-19 years).

The reliability of the individual methods varied as a consequence of the statistical techniques they employed. Regression-based aging methods are prone to producing estimates biased in the direction of the known age of the reference sample because the predicted ages are set by the mortality distribution of the reference population, which may not be comparable to other populations. Bayesian estimation avoids that tendency because it calculates both the mortality distribution of the reference sample and the test sample's age estimates. Rissech et al., the only method to employ Bayesian estimation, had the most reliable results because it was the most accurate method applied, with the smallest margin of inaccuracy and bias. The results suggest that Bayesian prediction may improve age estimation significantly and following further assessment should be applied to other age indicators.

Forensic Anthropology, Age Estimation, Adult Pelvis

A5 Plaque and Projections: Assessing the Utility of Morphological Variants of the Sternal Fourth Rib for the Estimation of Sex and Age-at-Death

*Andrew C. Seidel, MA**, Arizona State University, Human Evolution/Social Change, PO Box 872402, Tempe, AZ 85287-2402; *Laura C. Fulginiti, PhD*, Forensic Science Center, 701 W Jefferson, Phoenix, AZ 85007; and *Kristen Hartnett, PhD, OCME*, Forensic Anthropology, 520 1st Avenue, New York, NY 10016

After attending this presentation, attendees will better understand the statistical associations between biological sex, age-at-death, and the presence of bony plaque and/or central projections within the sternal pit of the fourth rib.

This presentation will impact the forensic science community by providing data suggesting that osseous anomalies of the sternal end of the fourth rib may profitably be employed in the estimation of sex and age-at-death from isolated ribs deriving from unidentified decedents, thereby allowing construction of a biological profile where more commonly used skeletal elements (e.g., cranium and os pubis) are unavailable.

This research was conducted using the Hartnett-Fulginiti collection housed at the Forensic Science Center in Maricopa County, AZ. This collection is comprised of more than 600 specimens of pubic symphyses and associated sternal ends of the fourth ribs from decedents of known sex, age-at-death, and ancestry. A total of 557 individuals (375 males and 182 females) ranging in age from 18 to 99 years were evaluated for the presence of bony plaque and central projections in the sternal pit of the fourth rib. Rib ends were independently assessed by two experts and consensus opinions on the presence or absence of plaque and projections were recorded. In addition, the presence of bony plaque was subdivided into three distinct morphological categories (Grades 1, 2, and 3) and, where sample sizes permitted, each category was independently assessed for associations with sex and age-at-death.

Results suggest that neither the presence of central projections nor that of plaque are independent of biological sex (projections: $\chi^2=37.5257$, $df=1$, $p\text{-value}=9.022e-10$; plaque: $\chi^2=80.9211$, $df=1$, $p\text{-value}<2.2e-16$). Based on the sample proportions, the probability that an individual exhibiting central projections is female is 0.775 with an associated 95% Confidence Interval (CI) of 0.623 to 0.879. Likewise, the probability that an individual exhibiting bony plaque is female is 0.717 with an associated 95% CI of 0.621 to 0.797. A more complex association is apparent when the occurrence of plaque is subdivided morphologically. All individuals in this sample exhibiting Grade 1 plaque are female ($n=7$), but sample size is too small to permit statistical validation. There is a 60.4% chance that an individual exhibiting Grade 2 plaque is female, but the associated 95% CI (0.463 to 0.730) suggests that this form of plaque is equally likely to be found in both males and females. However, there does appear to be age discrepancies between males and females exhibiting this plaque morphology such that Grade 2 individuals who are older are more likely to be female (95% CI: 0.562 to 0.962). The probability that an individual exhibiting Grade 3 plaque is female is 0.791 with a 95% CI of 0.646 to 0.888.

Similarly, the age distributions of individuals exhibiting central projections or bony plaque are statistically different. The mean age of individuals with projections (74.68, $n=40$) is higher than that of unaffected individuals (52.14, $n=463$) (Mann-Whitney: $U=3428.5$, $p\text{-value}=3.78e-11$). While the mean age of individuals exhibiting any form of bony plaque (54.41, $n=404$) is not statistically different from that of unaffected individuals (51.81, $n=98$) (Mann-Whitney: $U=21998.5$, $p\text{-value}=0.08735$), investigation of the association of specific plaque morphologies with age-at-death suggests more useful patterning. Results of a Kruskal-Wallis test indicate that the age distributions for each morphological grade of plaque and for unaffected individuals are not the same ($H=34.944$, $v=3$, $P=2.2e-16$). Post-hoc tests using Dunn's non-parametric comparisons indicate that the mean age of individuals with Grade 2 plaque (35.02, $n=47$) is significantly lower than that of unaffected individuals (54.41, $n=404$) and that the mean ages of individuals exhibiting Grade 1 (36.86, $n=7$) and Grade 2 morphologies is significantly lower than that of Grade 3 individuals (72.84, $n=43$).

These results suggest that, although far from ubiquitous, the presence of central projections and the formation of bony plaque within the pit of the sternal ends of fourth ribs may be useful in estimating both age and sex in unidentified remains for which more commonly used skeletal elements are missing or damaged. Further research is both required and encouraged to see if the associations identified here are present in other known-age skeletal collections and to assess the accuracy of using these morphological features of sternal rib ends for the estimation of sex and age-at-death.

Sternal Fourth Rib, Age-at-Death, Sex Estimation

A6 Sex Determination Using the Distal Articular Surface of the Fibula

Michelle U. Tabencki, MA*, Bone Clones, 21416 Chase Street, Ste 1, Los Angeles, CA 91304

The goal of this presentation is to demonstrate the use of the distal fibula to sex human skeletal remains.

This presentation will impact the forensic science community by offering a new method for determining the sex of human skeletal remains.

In forensic and anthropological literature, the fibula has not been extensively explored for its potential to determine sex. A study conducted by Sacragi and Ikeda used a population-specific discriminant function to correctly classify Japanese males at 90.1% and Japanese females at 91.4%.¹ This study investigates the distal fibula for its potential to sex Caucasian American skeletal remains. A population-specific discriminant function was developed using a Caucasian sample from the William M. Bass Donated Skeletal Collection. This formula correctly classified 85.2% of females and 89% of males using the left distal fibulae. Intra-observer analysis indicated a percentage error of 1.3%. While age had a slight effect on the measurements, it did not produce a significant effect to inhibit sex determination.

This study included both right and left fibula to determine which side yielded greater accuracy. A total of five measurements were taken of the distal articular surface of the fibula; three perpendicular aspects that form the malleolar surface (PA, PB, PC), total length of the lateral malleolus (LLM), and width of the malleolar fossa (LMF). These measurements combined to produce the discriminant functions that follow. The function for the left fibula is $DF = -14.953 + 0.242(LMF) + 0.253(PA) + 0.169(PC) + -0.055(PB) + 0.214(LLM)$. Scores above 1.0765 are determined male, below -0.8435 are determined female, and scores in between are indeterminate. The function for the right fibula is $DF = -15.128 + 0.253(LMF) + 0.331(PA) + 0.141(PC) + -0.081(PB) + 0.200(LLM)$. Scores above 1.0805 are determined male, below -0.8395 are determined female, and scores in between are indeterminate.

While significant age-related changes were not visible on the distal articular surface of the fibula, regression analysis did indicate that age had some influence on the fibular measurements. The analysis of a younger age bracket and an older age bracket demonstrated that the left fibulae had a smaller percentage of measurements affected by age. Examination of the literature demonstrated that few age-related skeletal changes occur on the articular surface on the distal fibula. This is due to thin articular cartilage and uniformity of cartilage matrix in the ankle, both of which contribute to a rarity of osteoarthritis in the area.

It is believed through this study that the method developed here should be used if the distal fibula is found, with preference given to the left fibulae. The discriminant formula should be used if the remains are suspected to be those of a Caucasian individual. While age does have some effect on the measurements, this technique is not age-dependent and can be used on suspected younger and older individuals. Additionally, low intra-observer error indicates the ease at which this technique can be performed.

A7 The Frontal Bone as a Proxy for Sex Estimation in Humans: A Geometric Morphometric Analysis

Lucy A.E. Hochstein, MA*, OCME Western District, 6600 Northside High School Road, Roanoke, VA 24019

After attending this presentation, attendees will gain an understanding of how to use a digitizer in sex estimation of the frontal bone using geometric morphometric analyses.

This presentation will impact the forensic science community by providing a means by which to estimate sex from fragmentary and/or commingled remains using existing technology to complement established methods.

This study combines visual assessment of the human skull with statistical methods of shape analysis, geometric morphometrics, to reach a better understanding of how cranial variation of the frontal bone is influenced by sex. Additionally, a sex-estimation technique was developed and assessed based on a single curve collected from the midline of a human frontal bone using a Microscribe® digitizer.

A sample of 204 crania from the Terry Collection at the Smithsonian Institution's National Museum of Natural History was studied. Male and female individuals of Black and White ancestry were selected to encompass sexually dimorphic variation between these ancestries. A visual assessment of cranial sex was performed using the glabellar scoring technique prior to the digital capture.¹ Following the example of previous cranial and brain outline studies, landmarks and semi-landmarks were collected from the frontal bone to form an outline of the frontal profile.²⁻⁴ Coordinate data for individual crania were imported into MorphoJ et al., a 3D, geometric morphometric visualization and analysis software package.⁵ The raw frontal bone outlines, composed of three landmarks and a curve resulting from varying numbers of points spaced every five millimeters, were re-sampled to have equal numbers of landmarks and semi-landmarks. To focus on shape variation, differences in size, position, and skull orientation were removed through a Generalized Least Squares Procrustes Analysis (GPA) superimposition algorithm. Curve shape was standardized by shrinking or stretching the individual curves, based on a calculated average curve length from nasion to bregma. Before statistical analyses were performed, digitized outlines of 12 individuals were deleted that, after visualization, did not appear to represent any natural frontal bone shape. Two geometric morphometric statistical packages, geomorph and MorphoJ, were used to conduct statistical analyses to understand variation in the collected frontal bone outlines and suggest the potential of this digitizer method for use in sex estimation.^{6,7} For all tests, significance was determined if $p < 0.01$.

Plotting of Principal Component (PC) scores on PC1 for all specimens shows a distinct pattern when the sex of individual skulls is labeled. Males are more scattered and females cluster in the negative portion of the graph. Similar to the Principle Component Analysis (PCA) plot, Canonical Variates Analysis (CVA) plots show males are more widely distributed and females cluster. Both the initial Discriminant Function Analysis (DFA) and the leave-one-out cross-validation show that the classification method presented in this study is better able to accurately classify females than males. In the cross-validation, females were correctly classified 88.3% of the time compared to males at 70.4%. Results of sex assessment based on the visual scoring technique corresponded fairly well to known sex. Out of the 192 curves, 69 (73.4%) of the 94 females were scored correctly as 1 or 2 and 13 (13.8%) were intermediate. Of the 98 males, 62 (63.4%) were scored correctly as 4 or 5 and 23 (23.4%) were intermediate.

Conducting this study laid the foundation for a future software package that may involve only a simple stroke of a digitizer pen on a frontal bone and the likelihood of that individual being male or female will be given immediately. Future research will expand the dataset to broader ancestry and age groups and include more modern (i.e., contemporary) individuals before testing begins on forensically significant collections. Additionally, this geometric morphometric technique has the potential to explore cranial sex differences in subadults, as has been demonstrated in innominates.⁸ Refinement of this method and inclusion of a broader sample may improve the classification rates of males and females and make this a useful technique to complement visual assessments of sex from the skull, especially when encountering fragmented and commingled remains.

Sex Estimation, Geometric Morphometrics, Frontal Bone

A8 A Qualitative Assessment of Bilateral Pubic Symphyseal Face Asymmetry Using the Suchey-Brooks Method for Adult Age-at-Death Estimation

Amy C. Beresheim, MA, 3152 Douglas Drive, Yorktown Heights, NY 10598*

After attending this presentation, attendees will gain an understanding of how bilateral asymmetries influence age-at-death estimations using the Suchey-Brooks Method.

This presentation will impact the forensic science community by serving as a follow-up to Overbury et al., further exploring how intra-observer error contributes to differing age-at-death estimates between right and left pubic symphyseal faces using the Suchey-Brooks Method.^{1,2}

Accurate and precise age-at-death estimation is critical to the construction of a biological profile in both forensic and archaeological contexts. Most methods for adult age estimation have been developed using North American skeletal collections from the early to mid-20th century and are based on progressive developmental and degenerative changes in bone tissues. Recent research indicates that these morphological skeletal changes may progress asymmetrically, complicating age-at-death assessments when there is a discrepancy between right and left pair elements or when age indicators are unilaterally represented.¹

The pubic symphysis is often considered the best indicator of skeletal age.^{3,4} Given its widespread use, the Suchey-Brooks method for adult age-at-death estimation was selected to qualitatively examine asymmetry of the os pubis.² For direct comparison with previous research, the method of recordation and the definitions of asymmetry followed Overbury et al.¹ The study sample was comprised of 142 White males from the J.C.B. Grant Collection, curated at the University of Toronto. This includes all of the male skeletons in the collection with well-preserved right and left pubic symphyseal faces. The documented age range of the sample is 23-90 years, with a mean age of 60.9 (\pm 15.1 SD) years. This study tests the accuracy of the Suchey-Brooks Method on a known age sample and evaluates whether pubic symphyseal face antimeres produce differing age estimates. This study explores whether bilateral asymmetry is a source of error in the Suchey-Brooks phase system.

Contrary to Overbury et al., asymmetries did not appear to affect adult age-at-death estimations using the Suchey-Brooks Method.¹ Individuals were placed into the “correct” Suchey-Brooks phase 64% of the time, irrespective of side. (Phase scorings were considered “correct” when specimens were assigned to the phase with the mean age closest to the verified age). Phase scores, as well as inaccuracy and bias scores, for the right and left pubic symphyseal faces are not statistically different. Asymmetry and intra-observer error was found to be correlated, suggesting that user experience may influence the prevalence of disparate age estimates between right and left pair elements. While this study does not preclude the existence of bilateral asymmetries at the pubic symphysis, quantitative work on pelvic asymmetry suggests that bilateral differences are likely to be inconsequential in an asymptomatic population and rather manifest as measurement artifacts.⁵ This would indicate that the differences between the left and right sides are more likely to be due to observer error (or random chance) rather than an actual effect of pelvic asymmetry itself.

In order to provide the most reliable age-at-death estimations, antimeres should be analyzed together whenever possible. If this is not possible, the use of either the right or left pubic symphyseal face seems justified.

Future research directions include expanding the study sample to incorporate additional younger adults, females, and multiple ethnicities. It would also be interesting to couple qualitative with metric assessments of asymmetry, as well as to examine the correlations between pelvic asymmetry and asymmetries of the lower limb.

Pubic Symphysis, Pelvic Asymmetry, Skeletal Aging Methods

A9 Visual Analysis of Maxillary Sinus Variability for Identification of Unknown Decedents

Kelsey Collins, BA, 7388 County Road 41, Willows, CA 95988*

After attending this presentation, attendees will gain an understanding of a method of decedent identification using comparison of the maxillary sinus region of antemortem and postmortem panoramic dental radiographs.

This presentation will impact the forensic science community by providing forensic professionals with an additional method of making a positive identification of an unknown individual.

Positive identification of unknown decedents is of great importance in any investigation. This process is often made difficult by a lack of antemortem records for comparison. A variety of positive identification methods using radiographic comparison of various anatomical structures have been extensively studied to combat this limitation, but many of these methods focus on comparisons of radiographs that are not common in antemortem records and can only be used in isolated cases. Standard dental radiographs are commonly used to make positive identifications of unknown remains because of their availability in antemortem records, but these identifications focus on the dentition of the individual. In recent years, panoramic dental radiographs, which allow for the examination of both dentition and a large portion of the maxillary and mandibular regions, have been commonly included in the standard dental exam. Along with providing a more global view of the dentition, panoramic radiography also provides a clear view of the maxillary sinus region. Several pilot studies suggest that panoramic dental radiographs could be used to compare a number of anatomical structures within the facial region of the cranium if dental identification was not successful; however, the use of these structures in the positive identification process has not been fully researched.

The purpose of this study was to examine the maxillary region of a known sample of pairs of panoramic radiographs from seven individuals, looking specifically at the maxillary sinus region visible on the radiographs for both congruency and corresponding unique traits between the pairs of radiographs. This sinus region was chosen due to the previous success of studies on positive identification using radiographs of the frontal sinuses and maxillary sinuses. To examine this, the dentition was cropped out of each radiograph, and an online survey was created that showed radiographs one at a time and allowed for the selection of a match for the radiograph from a group of four possible radiographs. Forty-nine participants completed both the radiograph matching survey and a brief questionnaire noting qualifications and level of experience.

The results indicated that the maxillary region of panoramic radiographs can be matched with an average of 80% accuracy, indicating moderate success in positive identification. Accuracy for matching the radiographs was not significantly higher for the participants with more experience. In examination of the sinus area, four anatomical structures were most associated with being diagnostic of a positive match: (1) the laterobasal border of the nasal cavity; (2) the inferior nasal conchae; (3) the borders of the eye orbits; and, (4) the maxillary sinuses. These results indicate that the maxillary region of panoramic dental radiographs has the potential to be used for positive identification purposes in the field of forensic anthropology and should be pursued further due to high inclusion of panoramic radiographs in the antemortem record. Future studies will further evaluate this region with both geometric shape analyses and visual matching assessments.

Maxillary Sinuses, Positive Identification, Radiograph Comparison

A10 Success Rates of Sex Estimation by Forensic Anthropologists Using Real-Life Forensic Casework Data

Richard M. Thomas, PhD, FBI Laboratory, Trace Evidence Unit, Rm 3210, 2501 Investigation Parkway, Quantico, VA 22135; Connie L. Parks, MA, 2501 Investigation Parkway, Laboratory Division, Quantico, VA 22191; and Adam H. Richard, MA, FBI Laboratory, 2501 Investigation Parkway, Quantico, VA 22135*

The goal of this presentation is to provide attendees with an understanding of the success rates of sex estimation of skeletal remains by forensic anthropologists through comparison with DNA sex-typing results in real-life casework data.

This presentation will impact the forensic science community by providing insight into the success rate of sex estimation from skeletal remains in various contexts, including the completeness of the remains available for analysis, the education and experience level of the anthropologist, and specific methods used for sex estimation.

A common task in forensic anthropology involves the estimation of the biological sex of a decedent based upon examination of their skeletal remains. Various methods for making this estimation, both morphological and metric, have been developed by exploiting the sexual dimorphism between males and females. These methods are often based upon analysis of skeletal collections of known sex and most include a theoretical success rate derived from the ability of the method to discriminate between males and females found in that skeletal collection. Often, methods are also tested on geographically and temporally diverse skeletal collections to determine how well the methods apply to groups other than the ones on which they were developed; however, the success rates of sex estimation methods in actual forensic casework have rarely been studied.

The research described in this presentation used sex determinations based upon the DNA results from the amelogenin locus from 360 actual forensic cases to develop “real-life” success rates for sex estimations conducted by forensic anthropologists based upon skeletal material. Cases included varying amounts of skeletal material available for analysis, varying levels of education and certification of the anthropologist, and information regarding specific techniques used for sex estimation. The overall rate of correct sex estimation from these cases is 94.7%, with increasing success rates as more skeletal material is available for analysis. For example, success rates varied from 60.0% when only the mandible was available to 87.5% when the cranium was available to 97.8% when a complete or nearly complete skeleton was available. Success rates also increased as the education level and certification status of the examiner increased. The difference in success rates between biologically male versus female decedents (as determined by DNA) was investigated and was not statistically significant. A large portion of incorrect assessments resulted from cases where only one skeletal element was available for analysis, suggesting caution should be employed, including more use of the category “undetermined sex,” when estimating sex for these types of cases.

Sex Estimation, Biological Profile, Human Osteology

A11 Quantifying Bias in Applying the Asian Equations of Trotter and Gleser to Korean Samples

Yangseung Jeong, MA, 560 Prestwick Ridge Way, #100, Knoxville, TN 37919; Lee Meadows Jantz, PhD, University of Tennessee, Dept of Anthropology, 250 S Stadium Hall, Knoxville, TN 37996-0720; Eun Jin Woo, PhD, Seoul National University, Dept of Anthropology, San 56-1, Silim-dong, Kwanak-gu, Seoul, SOUTH KOREA; and Yu Ryang Jang, PhD, 65 Hyeonchung-ro Donggak-dong, Donggak-gu, Seoul 156-080, SOUTH KOREA*

After attending this presentation, attendees will appreciate the magnitude and cause of potential bias in applying Trotter's and Gleser's Asian equations to Asian samples, particularly Korean samples, and therefore be aware of the necessity of testing for a magnitude of bias prior to applying those equations.¹

This presentation will impact the forensic science community by conducting a validity test for Trotter's and Gleser's Asian stature estimation equations, which are most popularly used in Asia, and by quantifying the amount of potential errors associated with their application to Asian samples. In addition, this research provides a theoretical basis for the potential bias.

Although the Asian equations of Trotter and Gleser have been widely used to estimate stature from skeletal remains of individuals with Asian ancestry, validation tests for those equations have rarely been performed.¹ In this research, accuracy of Trotter and Gleser equations was tested to quantify the degree of bias when they are applied to one of the Asian populations, Korean skeletal remains of the Joseon period (late 14th century to 1910) and the 20th century.

In stature estimation, the anatomical methods are generally known to produce more accurate estimates compared to the mathematical methods (i.e., regression formulas). Thus, statures of a total of 113 Korean skeletons (50 females and 63 males) were estimated using the revised Fully method by Raxter et al., which were assumed to be true statures.² Then, statures estimated by the Trotter and Gleser Asian equations were compared to these anatomically reconstructed statures. Although Trotter and Gleser provided only male equations, the equations were applied to female skeletons also for a comparison purpose.

Results revealed that male statures estimated by Trotter and Gleser were overestimated in all bone dimensions used: on average, 2.3cm, 1.3cm, 2.2cm, 3.0cm, 1.8cm, and 2.5cm for the equations using the femur, tibia, sum of femur and tibia lengths, humerus, radius, and sum of humeral and radial length, respectively. Percent prediction errors (i.e., (true stature - estimated stature) x 100/estimated stature) for each bone dimension were -1.4%, -0.8%, -1.4%, -1.8%, -1.1%, and -1.5%, respectively. When Trotter and Gleser equations were applied to Korean female skeletons, the magnitude of overestimation became larger: 6.5cm, 6.7cm, 6.3cm, 7.8cm, 5.2cm, and 5.6cm for the equations using the femur, tibia, sum of femur and tibia lengths, humerus, radius, and sum of humeral and radial lengths, respectively. Percent prediction errors for each bone dimensions were -4.2%, -4.3%, -4.1%, -5.0%, -3.7%, and -3.4%, respectively.

This bias (i.e., overestimation) appears to be attributed to a combinatory effect of both the extrapolated application of the Trotter and Gleser equations and the allometric nature of the relationship between stature and long bones. The average statures of the Korean samples were significantly lower than that of the reference sample in Trotter and Gleser (i.e., 168.73cm) by 6.51cm (3.6%) and 20.01cm (11.9%) for males and females, respectively. Thus, many of the Korean male samples and most of the Korean female samples fell in the left side of extreme cases or extrapolation cases in terms of the reference sample of Trotter and Gleser. Generally, the Ordinary Least Squares (OLS) regression, which was used in the process of equation development of Trotter and Gleser, is known to produce biased estimates for extreme cases (Konigsberg et al.), which is the case of the Korean skeletal samples.³ In addition, due to the allometric nature between stature and long bones, the slopes of the Trotter and Gleser equations were smaller than the actual relationship between stature and bone lengths of Korean samples. As a result, the degree of bias became larger as stature got smaller in Korean samples.

In applying the Trotter and Gleser equations to Asian populations, it appears necessary to compare the bone lengths of target samples to those of the reference sample of Trotter and Gleser prior to applying the equations and to be aware of the potential magnitude of bias associated with the equations.

Stature Estimation, Trotter and Gleser, Korean

A12 A Pilot Study Investigating 3D Variation in the Frontal Sinuses

Sarah M. Richer, MA, 16 Morley Avenue, Winnipeg, MB R3L 0X4, CANADA*

After attending this presentation, attendees will have an understanding of the issues plaguing current 2D methods to evaluate frontal sinus uniqueness and the potential of 3D approaches to visualize morphological variation.

This presentation will impact the forensic science community by providing a greater understanding of morphological variation which will enhance quantitative methods aimed at capturing individual uniqueness in these structures.

Identification of unknown individuals is an important aspect in forensic cases. The frontal sinuses are among several areas in the skeleton that have been proposed to aid in identification. These structures have long been considered unique to each individual because of the high degree of observed morphological variation. The most basic approach to compare the morphology of the frontal sinuses for personal identification purposes is either side-by-side comparison or superimposition of radiographic images taken of the frontal sinuses from similar angles and with similar magnification. This simple approach has given way to several methods that attempt to quantify observed morphological variation in the frontal sinuses.

A recent test of three methods on an independent sample revealed that these methods were not able to produce unique matches in all cases.¹⁻³ One explanation could be the predominant reliance on 2D data. To date, 3D variation in the frontal sinuses has only been explored in a single study which utilizes a coding system and reports two individuals in the sample produced the same ten-digit code.⁴

This study utilized an anonymized postmortem Computed Tomography (CT) sample of 130 individuals (males n=70, females n=57, unknown n=3) from the University of Copenhagen. The age range of the sample based on medical records is 19 to 88 years (mean males 49.9 years, mean females 54.9 years). The 3D rendering of the frontal sinuses was carried out using Materialise Mimics® for all individuals twice, permitting comparisons to be made between the same individual (different renderings). Ten trials were conducted using random groups of individuals. In nine trials, the second rendering of the primary individual was present and in one it was not. Stereolithography (STL) files were imported into Rapidform XOV3™ 64 and aligned with a sampling ratio of 100%. A whole deviation function was performed with a tolerance of zero. The tolerance value represents the amount of deviation from the target. By setting the tolerance to zero, any difference in size or shape between two frontal sinuses being matched was identified.

It was found that the mean overall out-of-tolerance percentage for same-skull comparisons was lower (16.24%, std dev 0.31) than that of the different skull comparisons (83.72%, std dev 1.29). Whenever the matching target render of the frontal sinus was present in the sample, it showed the lowest out-of-tolerance statistics and there was no overlap in the values between the same skull comparisons and the different skull comparisons. This is consistent with the assumption that two separate renderings of the same individual's frontal sinuses will be more similar to each other than renderings of frontal sinuses from two different individuals.

This preliminary study illustrates the potential for 3D quantification of variation and uniqueness seen in the anatomy of the frontal sinuses. Previously developed methods aimed at quantifying morphological variation have not been entirely successful because they attempt to reduce the variation seen in the frontal sinuses to a fixed number of variables or regions. Preliminary analysis shows that the variation is a function of both size and shape in all three dimensions and is not confined to specific regions of frontal sinus anatomy, viewable on 2D images. These findings highlight an important limitation to consider when developing and assessing methods and establish an explanation for why 2D methods are not fully capable of capturing the individual uniqueness present in these structures. Further methodological development needs to be carried out to improve the alignment procedure, including testing the use of specific landmarks and increased standardization in rendering. These 3D approaches to evaluating the uniqueness of frontal sinus morphology show promising results and represent future directions for research on personal identification.

Frontal Sinuses, 3D Comparison, Personal Identification

Anthropology Section - 2015

A13 Use of Measurements Derived From Computed Tomography (CT) Head Scans of Modern Americans for Comparison to the Forensic Data Bank of FORDISC® 3.0

*Terrie Simmons-Ehrhardt, MA**, 903 Watch Hill Road, Midlothian, VA 23114; *Christopher J. Ehrhardt, PhD*, Virginia Commonwealth University, Dept of Forensic Science, 1015 Floyd Avenue, Rm 2015, Richmond, VA 23284; and *Keith L. Monson, PhD*, 2501 Investigation Parkway, Quantico, VA 22135

After attending this presentation, attendees will understand how a diverse, modern American population of Computed Tomography (CT) head scans compares to the Forensic Data Bank (FDB). Attendees will also learn about some of the issues encountered when attempting to collect traditional craniometrics from CT scans of living individuals, which tend to be at a lower scan resolution than those collected from cadavers or dry skulls.

This presentation will impact the forensic science community by demonstrating the applicability of CT data in multivariate analyses such as those in FORDISC®. The results suggest that clinical CT scans may be a valuable source of additional population data to enhance anthropological analyses; however, further research is needed to explore how best to replicate traditional craniometrics in clinical CT scans where certain landmarks are typically difficult to locate.

This study presents the first comprehensive population comparison of CT scans of living individuals (n=291) to the FDB of FORDISC® 3.0. Landmarks were placed on rendered 3D models of the skulls of both sexes and three self-identified ancestry groups (African, Asian, and European) using Mimics® software in an attempt to replicate traditional cranial measurements. Triplicate placement of landmarks on a subset of skulls representing all the CT protocols in the sample found landmark errors of <2.1mm Standard Deviation (SD) (excluding euryon) and an average Interlandmark Linear Distances (ILD) error <1.7%. Euryon was found to be the least precise landmark, primarily in the z-axis (SD=4.1mm), but the imprecision of the landmark did not affect the precision of Maximum Cranial Breadth (XCB) (average error of 0.17%).

For comparison to the FDB, individuals were classified in FORDISC® twice, against all FDB populations and then against those of the same sex in accordance with other population-level studies using FORDISC®. In the all-group comparison, average classification accuracies ranged from 53% for sex and ancestry, to 65% for ancestry, and 81% for sex. The highest accuracy rates occurred among white females for ancestry (91%) and sex and ancestry (77%) and Asian males for sex (100%). When only same-sex groups were compared, classification to the correct ancestry was around 65%. In general, the Asian individuals classified with the least accuracy, but also represent a more diverse set of nationalities than those represented in the FDB. Expansion of the Asian groups in the FDB may enhance the classification of Asian Americans such as those in this study. Correct classifications of CT measurements occurred at above-chance frequencies that were comparable to FORDISC's® own cross-validation rates of the FDB using the same variables. In a comparison of group means for the 17 ILDs included in the FORDISC® analysis, CT scan values tended to be larger than FDB values. Orbital Breadth (OBB) had the largest difference across all groups, suggesting that the way this ILD was collected in this study was problematic due to the inability to locate dacryon. This study reveals that clinical CT scans may be a valuable source of anthropological data provided that the appropriate landmarks can be located. The above-chance classification rates and the low landmark placement/ILD errors suggest the multivariate relationships among FDB individuals can be used to estimate the sex and/or ancestry of modern American individuals using CT scans, opening the possibility for expanded use of CT data in anthropological analyses.

A14 The Effects of Household Bleach on Bone in the Processing of Forensic Remains

*Bobbie J. Leeper, MS**, University of Pittsburgh, Dept of Anthropology, 3302 Wesley W Posvar Hall, Pittsburgh, PA 15260; *Michael I. Siegel, PhD*, University of Pittsburgh, Dept of Anthropology, 3132 Wesley W Posvar Hall, Pittsburgh, PA 15260; *Margaret A. Judd, PhD*, University of Pittsburgh, Anthropology Dept, 3302 Wesley W Posvar Hall, Pittsburgh, PA 15260; *Sarah E. Henderson, PhD*, University of Pittsburgh, Dept of Oral Biology, 566 Salk Hall, Pittsburgh, PA 15260; and *Alejandro J. Almarza, PhD*, University of Pittsburgh, Dept of Med-Oral Biology, 566 Salk Hall, Pittsburgh, PA 15260

After attending this presentation, attendees will understand the effects of household bleach on the gross appearance of bone and trauma marks and its effect on the stiffness of bone.

This presentation will impact the forensic science community by describing the effects of a commonly used defleshing method on bone as well as by presenting a method by which to compare the biomechanical properties of bone prior to and following the defleshing process.

Individuals processing human remains from forensic cases are confronted with the unique challenge of choosing a defleshing method that is non-destructive to bone in order to preserve identifying features and fine marks of trauma, while remaining within the time constraints of a legal setting. Sodium hypochlorite (NaOCl), an oxidizing agent, in the form of household bleach such as Clorox[®], is used in some laboratories to speed the process of defleshing and as an additional disinfectant. Household bleach is popular among many researchers due to its easy availability and low cost. Some have claimed that while other chemicals are harmful to bone tissue, household bleach is safe enough for human forensic cases, even those exhibiting signs of peri-mortem trauma.¹ Nawrocki intimates, due to health safety issues, that biohazardous remains must be simmered in water with bleach before entering the main osteology laboratory to be handled for analysis.² Despite these claims, others assert that bleach is too harsh to be used on bone.³

The goal of this study is to describe and compare two commonly practiced methods of defleshing human remains — plain water boiling and boiling with Clorox[®] bleach — in order to assess the effects of bleach on bone tissue. Three concentrations of Clorox[®] (low, medium, and high) were compared to the method of boiling in plain water. White-tailed deer (*Odocoileus virginianus*) distal hind-limb segments exhibiting knife-cut marks and saw marks (n=20) were used to test the effects of each defleshing method on the bone tissue and the appearance of sharp-force trauma on the bone, in addition to using them to test the effectiveness of soft tissue removal. The effectiveness of the method was assessed by comparing the quality of the end result and the time-to-completion for each method. The effects of the methods on the bone were assessed by noting the gross appearance of the bone and trauma marks prior to and following each processing method. Additionally, bone core samples were taken before and after processing to be used in a biomechanical test of the structural integrity of the bone tissue. An Instron[®] 5564 with a 2kN capacity was used to conduct unconfined compression tests to test the stiffness of the bone tissue of these bone core samples.

Each of the four defleshing groups took 6-8 hours to complete (M=6.55 hours, SD=0.605), with no statistically significant difference among the methods in time-to-completion. Moreover, comparison of the strain at 1790N, the first peak on the stress/strain graph, and the tangent modulus of the pre- and post-processing bone core samples revealed no statistically significant difference among the groups in the stiffness of the bone. However, cortical bone exfoliation was noted in two of the five high-concentration bleach samples.

In conclusion, the addition of bleach to heated tap water does not affect the time-to-completion or the stiffness of the bone, but, in high concentrations, can damage bone tissue macroscopically. Bleach is also known to lower the quality of DNA retrieval.⁴ Therefore, unless it is found that bleach can sterilize biohazards that boiling alone cannot, it should be avoided in forensic cases as it has the potential to damage bones if not used properly.

After attending this presentation, attendees will be aware of the macroscopic and microscopic effects of acid and basic solutions when used with the purpose of destroying a corpse and thus hindering discovery and identification.

This presentation will impact the forensic science community by highlighting the effects of acid and basic solutions on bone and the importance in correctly assessing their effectiveness in the destruction of tissues and in the modification of signs of trauma.

Among the different methods that are seldom used with the goal of destroying a corpse and thus preventing discovery or at least identification, the use of highly acidic or basic solutions is something forensic pathologists sometimes have to deal with, especially in criminal scenarios. Moreover, determining whether a bone (or even a single fragment) was in contact with an acidic/basic solution could be a crucial question posed to the anthropologist. Of all taphonomical modifications during decomposition processes, little is known about the action of high or low pH to human tissues and bones. The main question is, are these solutions able to make a cadaver completely “disappear” and, when human tissues come in contact with these substances, what kind of changes do they undergo? How are they recognizable? Only a few studies have focused on this issue and have referred only to macroscopic surveys.

In this study, a total of 60 samples of porcine bone (*Sus scrofa*) were completely skeletonized manually, without any chemical or other artificial treatment. Furthermore, on each sample, a cut mark was produced with a scalpel in order to evaluate the modifications that these signs can undergo in such conditions. Specimens were then divided in groups of ten each and put in six different liquid solutions with different pH (1, 3, 5, 9, 12, 14) prepared by adding sulfuric and acetic acids and sodium hydroxide to water. A neutral control solution (pH 7) was also prepared.

Specimens were analyzed every five days over a period of 70 days. The appearance of the outer cortical layer of the bone and the aspect of the cut marks were investigated first macroscopically and then microscopically with a Wild Heerbrug® M650 stereomicroscope and Scanning Electron Microscopy (SEM). Finally, thin undecalcified sections were prepared and analyzed with a transmitted light microscope in order to evaluate the changes of the osteonic structures and the appearance of characteristic patterns.

Regarding the macroscopic observation, minimal lytic modifications became evident in all the samples, but only those exposed to a pH 14 for a long time showed evident alterations of the cortical bone, such as large erosions and cracking. Cut marks showed alterations in 50% of the cases, especially when exposed to basic solutions, detectable as enlargements, distortions, or detachment of bone flakes.

The most interesting results arose from light microscopy of thin sections: if further significant elements were not gained with stereomicroscopy, scanning electron microscopy and light microscopy provided the most interesting results. The first enabled the observation of significant alterations on the surface of the cortical bone, with evident deposits of organic and inorganic matter as the pH became more acidic and as contact time increased. This layer of matter gives an important contribution to the macroscopic alterations of cut marks on bone which may, as in the case of pH 1 and 14, no longer be even recognizable.

Moreover, the study showed for the first time that, even without detectable macroscopic alterations, the osteon structure visible in light microscopy is severely deteriorated by acids and bases, frequently with peculiar patterns, like radial or multidirectional cracking. The information gained from the present study can be of great help in the detection of an exposure of human tissues to high or low environmental pH and in understanding the effects that these solutions can exert on human bones. Extreme pH can significantly alter the structure of human bone and make signs of traumas undetectable, but the contact between solutions and bone can be detected if thoroughly analyzed, especially through light microscopy.

Acids, Cadaver Destroying, Cut Marks

A16 Thermal Analyses of Property Changes and Weight Loss in Incinerated Bone and Their Implications for Forensic Anthropology

Sarah Ellingham, MSc, Teesside University, School of Science and Engineering, Middlesbrough TS1 3BA, UNITED KINGDOM*

After attending this presentation, attendees will understand how thermal analysis techniques such as Thermogravimetric Analysis (TGA) and Differential Scanning Calorimetry (DSC) can be utilized to glean information about the properties and phase transitions undergone by bone when exposed to heating.

This presentation will impact the forensic science community by investigating how exposure to varying temperatures and differing heating regimes affects the rate of compositional changes of bone and by discussing the implications for further forensic analyses such as dating, isotope analyses, and genetic profiling.

Many studies have demonstrated that bone undergoes three stages of degradation and weight loss during heat exposure, which are attributed to a loss of water, the combustion of organic components, and finally, the loss of carbonate and crystal fusion. Not so well understood is to what extent these processes are influenced by the heating regime or the duration of exposure. This study utilized time- and temperature-resolved TGA and DSC to investigate the temperature regions in which the main structural changes occur and how these are influenced. TGA measures the weight changes in a sample as a function of a temperature profile and DSC allows for the monitoring of the heat flow in and out of a sample, which allows for the detection of phase transitions in the material.

Sheep (*Ovis aries*) rib bones were cut into cross sections of approximately 20mg and analyzed using an Evisa® STA 1500 Simultaneous Thermal Analyzer. Samples were heated from room temperature to 1,100°C, for which three different heating rates were employed, 6°C/min, 12°C/min, and 24°C/min. Additionally, two sets of samples were heated at a rate of 12°C up to a maximum of 300°C and 400°C and held at these temperatures for 45 minutes. All runs were carried out in triplicate.

Although weight loss as well as the heat flow curve of the three different heating regimes exhibit comparable patterns, an approximately 25°C delay in the temperature onset of phase changes with every doubling of heating rate was observed. In order to find the temperature regions of increased weight changes the first derivative of the TGA curve ($\Delta_{\text{mass}}/\Delta_{\text{temp}}$) was calculated. Distinct peaks were noted at about 125 +/- 25°C, 375 +/- 25°C, 500 +/- 25°C, and 775 +/- 25°C at the heating rates of 6, 12, and 24°C/min, respectively. These observed weight changes correspond with the matrix phase alterations shown by the DSC. The initial heating phase corresponds to an evaporation of water, an endothermic process which peaks between 100°C and 150°C and continues up to a temperature of approximately 350°C, at which point the combustion of organic components commences, which introduces the exothermic process of the hydroxyapatite crystals becoming larger and more ordered. A brief endothermic phase attends the combustion of carbonate at about 450°C, which is followed by a strong exothermic phase as the bone's collagen continues to combust, spiking at approximately 500°C, and recrystallization of minerals proceeds. The process remains exothermic up to 750-800°C at which point the mineral begins to sinter and crystals melt in an endothermic event.

Not only did the increase in heating rate delay the temperature onset of the bone's phase transitions, but it also demonstrated an influence on the weight loss. At 1,100°C, the sample heated at 6°C min exhibited the gravest average weight loss with 59.6%, the one at 12°C lost 57.7%, and the sample heated at 24°C lost 51.1%. The observation that exposure time has an influence on the loss of mass is confirmed by the samples which were held at fixed temperatures for 45 minutes. Samples heated to 300°C, when initially reaching the temperature, lost 16.54% of their weight, which after 45 minutes increased to 33.32%. Samples held at 400°C started out with 35.2% mass loss which increased to 49.4%. The corresponding DSC curves indicate that although a steady loss of mass occurs, which is most likely attributed to the combustion of collagen, the bone does not undergo any further property changes if the temperature remains at the same level.

Being able to determine the point at which organic components in bone are lost is of crucial importance for forensic analyses, as successful collagen extraction is the basis to conduct isotope analyses, dating, or genetic profiling.

After attending this presentation, attendees will understand how decomposition can be affected by different soil environments, specifically human bone remains.

This presentation will impact the forensic science community by providing information on factors that influence bone alterations that are generated by burial. These alterations can be measured by the loss of bone mass to help pathologists in more accurately predicting the time-since-death on human remains in forensic settings.

A multitude of factors can affect each stage of the decomposition process by either accelerating the process or slowing it down. Variables in soil environments include moisture, temperature, pH, and scavenger activity.

An experiment was designed on four human ribs to document how moisture and temperature affect the bone weight related to the postmortem interval. Three of the ribs were buried and the fourth rib was placed in a controlled environment. Three human cadavers were used, and the R1, R2, R3, and R4 ribs were removed from each cadaver. All of the bones were manually defleshed, immediately weighed, and placed in their environments on the same day. The R1 and R4 ribs were buried outside in clay at a neutral pH, the R3 rib was buried in clay at a neutral pH under a hood at 20°C, and the R2 rib was placed under a hood at 20°C without clay as a control. Temperature and humidity were recorded daily. Ribs were weighed daily using a precision balance (Kern® ALT310-4, d=0.1mg). Daily weight loss of the three subjects (i.e., the percentage of remaining weight) were studied over 90 days and averaged depending on the burial environments.

Burial environments were compared by studying the distributions of bone weight loss using a Kruskal-Wallis test. Results showed there were significant differences between environments ($p < 0.0001$) for inside vs. outside burials and burial vs. control: bone weight loss was significantly faster inside (i.e., low moisture content and constant temperature) and without clay soil (i.e., without retaining moisture in the environment). Combined comparison tests were performed on a day-by-day, per environment basis using a Chi-squared test and Marascuilo's post-hoc procedure. The results showed there was a significant difference in bone weight loss ($p < 0.0001$) between the indoor and outdoor environments from day one to day five of the postmortem interval. This difference was less significant from day six ($p < 0.05$) and not significant from day ten. Bone weight loss continued and finally stabilized to approximately 50% of the initial mass at three months, regardless of the experimental conditions.

Bone tissue can be considered a composite material of an organic phase and mineral phase. An inorganic hydroxyapatite mineral is embedded in an organic matrix composed of type I collagen. Wet bone is composed of approximately 15% water, 20% organic, and 65% mineral portions by weight. The loss of bone mass can be explained primarily by the decrease in bone moisture content. The literature explained that the average ash percentage of bones increases dramatically but generally levels off. Moisture content decreases rapidly for nearly two months, after which the drying process continues at a slower rate. These observations are consistent with this study.

However, the loss of bone mass can also be explained by chemical and physical alterations of the tissue. The diagenesis of bone tissue is a multivariable process that affects mineral and organic phases. The mineral phase can undergo mineral precipitation, ion exchange, recrystallization, dissolution, and leaching. The organic phase is primarily associated with collagen loss due to chemical breakdown or microbial attack followed by leaching. The development of these phenomena should be better studied to understand the process of bone weight loss.

Postmortem Interval, Burial, Bone Moisture

A18 The Identification of Undocumented Border Crossers Along the United States-Mexico Border: A Case for Bone Histology

*Sophia Mavroudas, MA**, Texas State University, 601 University Drive, ELA 232, San Marcos, TX 78666; *Kate Spradley, PhD*, Texas State University, Dept of Anthropology, 601 University Drive, San Marcos, TX 78666; *James P. Fancher, DDS*, 345 Blue Lane, PO Box 682, Martindale, TX 78655; *Hailey A. Duecker, BA*, 12108 Lavinia Lane, Austin, TX 78753; and *Nicole M. Crowe*, 1600 Willow Way, Round Rock, TX 78664

After attending this presentation, attendees will understand the difficulties of identification along the United States-Mexico border and the benefit of using bone histology for age-at-death estimation on Undocumented Border Crossers (UBCs).

This presentation will impact the forensic science community by serving as a guide to improve the identification of UBCs in the growing humanitarian crisis afflicting the United States-Mexico border.

UBCs found along the United States-Mexico border present new challenges in identification as population-specific methods are lacking for this group. Since 2013, the Forensic Anthropology Center at Texas State (FACTS) has been working to identify UBCs exhumed from Brooks County, TX, led by Drs. Lori Baker and Krista Latham. As part of this effort, FACTS has accepted 73 UBCs from the Brooks County, TX, exhumations and from the Webb County, TX, Medical Examiner's Office. These UBCs are typically in early to late stages of decomposition and are held at the FACTS outdoor decomposition facility until they can be macerated and analyzed. While some of the UBCs have soft tissue, the majority of remains require skeletal analysis to generate the biological profile. The current ancestry estimates of the Texas UBCs, due to lack of appropriate reference data from Latin America, predominantly fall into the Hispanic category. While the Hispanic classification is useful in the identification of an unknown individual as a UBC, it does not assist in differentiating among self-identified racial/ethnic categories as in the United States, which can narrow down a list of potential matches from a missing persons' list. Therefore, a critical aspect of UBC identification is an accurate age-at-death estimate, to narrow the list of potential matches for identification.

The goal of this study is twofold: (1) to examine the protocol used for identification of UBCs at FACTS to determine if the current methods provide accurate estimates; and, (2) to ascertain if the addition of bone histology can assist in creating more accurate profiles. A case study is also presented to illustrate the need for more accurate age-at-death estimation methods for UBCs.

The remains of N=19 (10 males and 9 females) UBCs were assessed using morphological and histological methods. The morphological methods included dental development, pubic symphyseal and auricular surface morphology, and sternal ribs. Bone histomorphometry of the midshaft of the left 6th rib was analyzed using osteon population density methods.^{1,2} Agreement between the gross morphology and bone histology methods were assessed by recording whether the histomorphometric age ranges overlapped with the final gross morphological age ranges.

Results show that the histomorphometric estimates for all individuals overlapped with the gross morphology ranges (19/19=100%) suggesting that the microstructural age-related changes correspond with the visible morphological changes. Since many of the UBCs are unidentified, this test of agreement is necessary to support the use of bone histology for aging UBCs. When applying the two approaches to a UBC-positive Identification (ID), the morphological methods provided an age range of 20-35 years, but failed to capture the actual age of 38 years, likely due to the lack of fusion of all skeletal elements. However, histomorphometry provided an age range of 27-57 years, with a point estimate of 39.5 years. If the morphological estimate was the sole search criteria within a missing person's database, this individual may have remained unidentified. Combining the morphology with the histology estimate allows for a complete understanding of both the micro and macro skeletal age and provides a range that encompasses the known age of the UBC.

The results of this study indicate two important factors for UBC identification: (1) applying only traditional aging methods to UBC identification can fail to accurately predict age, likely due to the low socioeconomic status of these individuals and corresponding delayed development; and, (2) incorporating bone histomorphometry of the 6th rib more accurately reflects the age-at-death of the UBCs. By changing the protocol for UBC identification, the accuracy of the age-at-death estimates can be improved, the cost in time and money for identification of UBCs can be reduced, and the number of identifications could be greatly increased.

Undocumented Border Crossers, Bone Histology, Identification

A19 The Influence of Taphonomic Changes and Microstructure Varieties on Histomorphological Analysis in Species Determination

Katrin Koel-Abt, PhD*, JPAC-CIL, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853; and Miranda M. Jans, PhD, JPAC-CIL, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853

After attending this presentation, attendees will gain a better understanding of variations in microstructure of osseous remains and will be able to identify the characteristics of taphonomic changes on bone. This will aid in better accuracy at distinguishing inconclusive osseous remains (including human) from non-human osseous remains, enable a better understanding of taphonomy, and may significantly reduce the number of misinterpretations.

This presentation will impact the forensic science community by providing descriptions and examples of different taphonomic conditions as well as variations of bone microstructure between and within species. Example pictures will enable visual comparison and identification of structures and changes and will, therefore, enhance the accuracy of identifying non-human osseous remains.

It is generally a challenge to interpret degraded and fragmented osseous remains found during recoveries. Both biotic and abiotic processes can alter skeletonized remains after death and thus affect any identification analysis. The role of taphonomy and variation is often underestimated and, for this reason, can lead to misdiagnosis of bony fragments.

Histomorphological techniques used at the Joint POW/MIA Accounting Command-Central Identification Laboratory (JPAC-CIL) are applied to distinguish inconclusive osseous remains from non-human osseous remains. Chemical, biological, or physical activity can affect the condition of remains (e.g., environmental conditions, such as soil composition or microbes, as well as type-of-loss incident). Bone structure can differ between species, within individuals of one species, and even within a single bone, depending on numerous factors (e.g., growth speed, aging, diseases, biomechanical load, etc.). Bone tissue is a dynamic structure and subject to remodeling; for example, bone growth and bone resorption due to osteoblastic and osteoclastic activity on the micro-structural level. The histomorphology of bone is similar between genera within *Mammalia*. Fast growing mammals can show plexiform primary bone structure, a bone type that is not found in (slow growing) humans. Thus, a sample can be identified as non-human if plexiform bone structures are present.

Histomorphology at the JPAC-CIL uses standard histomorphological methods to distinguish inconclusive osseous remains (which can include human) from non-human osseous remains. But histomorphology can additionally aid in the identification of taphonomic processes and provides information regarding changes in the bone microstructure. The methodology for standard histological analysis at the CIL utilizes three consecutive processes: (1) embedding; (2) sectioning; and, (3) analysis of a sample. Basic epoxy embedding is used to stabilize the sample for thin sectioning. Then, using a precision saw, transverse thin sections of approximately 0.08mm thick are made, which are mounted and analyzed using a light microscope.

Difficulties in ascertaining with certainty whether a fragment is human or non-human arise when the original bone anatomy exhibits extensive alterations due to taphonomy, degradation, or changes in the microstructure because of bone remodeling. Microbial alteration can destroy the original microstructure to a point where it is no longer recognizable, whereas other processes like heating or diagenesis can reduce birefringence, cause cracking, and introduce foreign material into the bone matrix, all of which can complicate analysis.¹ Remodeling will replace primary bone with Haversian bone, in which case only the presence of organization (banding) of Haversian systems can indicate whether bone is non-human in origin.² Example photographs as well as possible solutions to these issues will be presented.

Histomorphology, Taphonomy, Species Differentiation

Anthropology Section - 2015

A20 **Stable and Heavy Isotope Analysis: The Successful Use of Chemical Research in the Tampa Bay Cold Case Initiative**

Liotta N. Dowdy, BS, University of South Florida, Dept of Anthropology, 4202 E Fowler Avenue, SOC 17, Tampa, FL 33620; Erin H. Kimmerle, PhD, University of South Florida, Dept of Anthropology, 4202 E Fowler, SOC 107, Tampa, FL 33820; and George D. Kamenov, PhD, University of Florida, Dept of Geological Sciences, 241 Williamson Hall, Gainesville, FL 32611*

After attending this presentation, attendees will understand the principles underlying heavy isotope analysis. Isotope analysis, utilized in forensic investigations, assists in the estimation of geographic origin and migration patterns of unidentified decedents. Isotope analysis has been utilized in bioarchaeology for decades. More recently, heavy isotope analyses involving strontium isotope and lead isotope ratios have been utilized in the estimation of geographic origins for migrant populations and unidentified decedents.

This presentation will impact the forensic science community by highlighting the importance of biogeochemical methods to enhance forensic anthropological investigations. This current research study will yield local strontium and lead isotope values that can assist with current unsolved cases for Florida and the southeast region of the United States.

Forensic anthropologists systematically apply a comprehensive set of methods for unsolved cases (i.e., the estimation of age, sex, ancestry, trauma, pathology, and unique identifying characteristics) to aid in the identification of decedents. Application of methods such as chemical and elemental analysis offers long-term unsolved cases new lines of evidence. These methods are proving to be valuable by yielding georeferencing information for the identification of victims.

Human teeth and bones are an archive of long-term strontium and lead exposure. Strontium and lead isotopes were analyzed from the teeth of unidentified individuals. Permanent teeth begin enamel mineralization during early childhood, as early as three to six months during infancy with central incisors and up to 12-15 years of age with the first permanent molars. Strontium is absorbed into the individual's biology via the food chain with the ultimate source being the local bedrock, soil, and water. Long-distance importation of food and water may affect the individual's strontium isotope ratios and may not be entirely controlled by the local environment. Similarly, the lead isotopic compositions of individuals can be linked back to local environmental sources of lead from the soil or from anthropogenic sources such as leaded gasoline.

In contrast to strontium, it is believed that lead is more directly absorbed through soil and/or dust ingestion or inhalation and, therefore, is not likely to be affected by importation of foods from other regions. A comparison of the isotope ratios of the enamel and bone can yield a pattern of migration from when the individual moved from one geographic region to another region throughout their lifetime. The enamel formation during early childhood gives a biochemical profile of the individual's early years, with bone remodeling over a course of 7-10 years continually as a person ages. The bone offers a biochemical profile of the individual's last years of life.

For this research, stable and heavy isotope analysis of $\delta^{13}\text{C}$ (carbon), $\delta^{15}\text{N}$ (nitrogen), $\delta^{18}\text{O}$ (oxygen), $^{87}\text{Sr}/^{86}\text{Sr}$ (strontium), and the lead isotopes ($^{206}\text{Pb}/^{204}\text{Pb}$, $^{207}\text{Pb}/^{204}\text{Pb}$, and $^{208}\text{Pb}/^{204}\text{Pb}$) were completed on current and cold cases, which includes a sample of 30 individuals (15 males, 10 females, and 5 unknown) since 2010. Stable isotopes of carbon and nitrogen were utilized to investigate diet and nutrition, while oxygen, strontium, and lead isotopes were used to evaluate geographic origin and environment. Isotopic analysis aided in identifying the individual's diet over their lifetime and the geography of their living environments. Heavy isotope results were instrumental in the estimation of the decedent's birth location versus where they were recovered in Florida.

In the cases of successful identification encompassed within the Tampa Bay Cold Case Initiative, the isotope results have successfully revealed geographic origins and migration patterns for the decedent. A trend in the isotope results also reveals numerous cases in the Tampa Bay region are foreigners or out-of-state individuals. From the isotope results for the unsolved cases, cold case investigators were able to redirect their investigations and reach out to other agencies with the new information concerning the case.

The Tampa Bay Cold Case Initiative is a noteworthy example of collaborative work and research by forensic anthropologists, scientists, and medicolegal agencies. The goal of this project is to reinvestigate and highlight "cold cases," which has led isotope analysis to be applied to recent skeletal cases due to the transient nature and population of the Tampa Bay region. Collaborative and multidisciplinary research is a key function for casework involving unidentified human remains.

Isotope Analysis, Cold Cases, Biogeoferencing

A21 A Preliminary Study for Estimating Postmortem Interval of Fabric Degradation in Central Florida

*Patrisha L. Meyers, BA**, 2565 Sykes Creek Drive, Merritt Island, FL 32953; *Lorraine Humbert, BA*, University of Central Florida, 4000 Central Florida Boulevard, Orlando, FL 32816; *John J. Schultz, PhD*, University of Central Florida, Dept of Anthropology, 4000 Central Florida Boulevard, HPH 309, Orlando, FL 32816; and *Lana Williams, PhD*, University of Central Florida, 4000 Central Florida Boulevard, Orlando, FL 32816

After attending this presentation, attendees will understand how forensic anthropologists can use degraded clothing in determining the extended postmortem interval of cases involving skeletal remains.

This presentation will impact the forensic science community by establishing standardized methodologies for the research and analysis of degraded clothing which have the potential of being used as a new method when estimating the extended postmortem interval.

Forensic anthropologists rely on a variety of evidence to estimate the Postmortem Interval (PMI) of a decedent, which includes gross decomposition rates, the life stages of insects, and the degradation of associated material evidence. The degradation of material evidence, in particular, is an underutilized area in estimating PMI. Degraded clothing is a common type of material evidence recovered in association with skeletonized remains that is also modified by taphonomic processes. While previous research has been undertaken regarding how degraded fabric can be used as a PMI indicator, there is no standard methodology for the research design or to quantify the extent of fabric degradation. The purpose of this project was to analyze the degradation of four different fabrics in central Florida and to develop a comprehensive scoring system and descriptive methodology to be used as a standard for scoring fabric degradation. In addition to providing standards for future research, the methods used in this project are applicable to the analysis of forensic cases.

Four types of fabric swatches were tested (100% cotton, 60% polyester/40% cotton, 100% rayon, and 100% cotton denim) at three different burial depths (ground surface, ~30cm below ground surface, and ~60cm below ground surface). Swatches were placed in six groups for each of the three different burial depths. Each group included a total of eight swatches, two of each fabric type (cotton, cotton/poly, rayon, and denim) that were arranged in two different positions, flat (horizontal) and crumpled. While there is no standard for fabric swatch size, this study utilized a 15cm x15cm-size swatch that is suggested as a standard research size. The swatches were washed and dried one time based on recommendations by Mitchell et al., who concluded that clothing found at a crime scene is unlikely to be unlaundered and brand new.¹ In addition, a meat source was incorporated from a butcher to more accurately reflect the degradation process of fabrics found in conjunction with a decomposing body. Combinations of microscopic and macroscopic methods were used to analyze the degraded swatches. These included a stereomicroscope to analyze warp and weft, the Munsell color system to document color changes, and a transparency overlay developed for this project to evaluate the percentage of material loss.

Groups of fabric swatches were retrieved at one-month intervals for the duration of six months. After retrieval, cotton exhibited the highest level of degradation, as one-third of all cotton fabric swatches demonstrated more than 50% total degradation. Furthermore, cotton fabric swatches degraded more at both ~30cm and ~60cm below ground surface than on the ground surface; however, all other fabric types demonstrated slightly more degradation on the ground surface than the other two areas. For all fabric types, swatches that were positioned flat tended to degrade more than those that were positioned crumpled. While soil moisture fluctuated the most on the ground surface, the soil at both ~30cm and ~60cm below ground surface depths retained increased moisture throughout the study period. Overall, cotton was the only fabric type to degrade significantly enough to demonstrate substantial degradation during the research period, while all other fabric types exhibited minimal degradation over six months of monitoring.

In forensic cases lacking soft tissue, degraded clothing is a common example of material evidence recovered at a crime scene with skeletal remains. Overall, this study has developed replicable standards that can be used for scoring and evaluating fabric degradation to be used as an extended PMI indicator. Understanding fabric degradation is critical to establishing a long-term PMI when confronted with skeletal remains and an area of research to consider in the future as forensic anthropologists continue to expand their interdisciplinary tool kit and stimulate new areas of research.

A22 Decomposition in Concrete: Los Angeles Style

Elizabeth A. Miller, PhD*, CSULA, Dept of Anthropology, 5151 State University Drive, Los Angeles, CA 90032; and Margaret A. Kaleuati, MS, 1104 N Mission Road, Los Angeles, CA 90033

After attending this presentation, attendees will understand how concrete impacts the decomposition process and the importance of a multidisciplinary team for investigation of concrete “burials.”

This presentation will impact the forensic science community by serving as an instructional guide to assisting in the determination of Postmortem Interval (PMI) for bodies recovered from concrete.

Disposal of human remains in concrete is a rare occurrence in Los Angeles County; however, interpretation of remains from such contexts may lead to significant information in homicide investigations. One of the important aspects of investigation is the determination of PMI. As with any estimation of PMI, many intrinsic and extrinsic factors must be taken into consideration. Despite these factors, an analysis of three cases recovered by the Los Angeles County Department of Medical Examiner/Coroner illustrates commonalities between bodies recovered from concrete.

Four commonalities were documented: (1) bodies, even when dismembered, are generally complete; (2) the concrete is generally poorly-mixed; (3) the bodies are secreted in a secondary fashion as well; and, (4) concrete may act as a preservative of both remains and identifying features.

Case 1 was an adult recovered from a sandy soil in the yard of a residence. The remains were buried in a shallow grave adjacent to the dwelling, clothed but without additional wrapping. A thin layer of poorly-mixed concrete was poured over the remains, but did not cover the entire decedent. Soil was placed over the concrete. The decedent was discovered approximately 13 years postmortem and was completely skeletonized, with excellent preservation of bone. The concrete preserved a mold of the face and one hand; from these preserved molds casts were made and fingerprints were obtained for positive identification of the decedent.

Case 2 was a child approximately four years old, wrapped in a plastic garbage bag, and encased in concrete in a cardboard box. The decedent was moderately decomposed, having been kept in a bathtub for four days, stored for a time in an ice chest over ice, then encased in concrete. The decedent was recovered from a car trunk approximately six months postmortem. The decedent was dismembered and showed skin and hair slippage, body fat liquefaction, and softening of the tissues, but was remarkably well preserved.

Case 3 was an infant recovered in a plastic bin wrapped in a plastic sheet and buried in a shaded area on public land. Scavengers had attempted to uncover the remains, but were prevented from doing so by heavy plastic sheeting. The decedent was clothed and in a disposable diaper, wrapped in a fleece blanket, placed on a folded second fleece blanket in the container, covered with a towel, and then covered with approximately seven inches of poorly mixed concrete. The container was sealed before the concrete fully set, leaving a moist, anaerobic environment for decomposition. The remains were recovered approximately one month after they were placed in the container and buried. The infant showed advanced decomposition changes in the area of the abdomen, with hard adipocere formation across the remainder of the body.

Based on these case studies, a preliminary hypothesis that concrete encasement slows the decomposition process was formed. Los Angeles County contains a minimum of five microclimate zones, including coastal, valley, mountain, high desert, and low desert. Temperature variations between the microclimates can be as much as 30°F and humidity differentials are dramatic between the coastal and desert areas. This leads to differences in the rates of decomposition between these microclimate zones. In general, decomposition studies conducted at California State University, Los Angeles in thesis research and personal experience demonstrate that, with the exception of the high desert and mountain zones during the winter months or in cases where mummification occurs, infants and children decompose rapidly, reaching skeletonization in as little as one week in some cases and rarely exceeding three months.

As these three cases illustrate, PMI for bodies in concrete is difficult to decipher because of the many extrinsic and intrinsic factors inherent in the decomposition process. It is hypothesized that the anaerobic environment and lack of insect access slow the decomposition process in concrete-encased bodies regardless of the state of decomposition when they are placed in the concrete. Additional research is currently underway to test the phenomenon of decomposition delay in concrete.

Decomposition, Concrete, Adipocere

A23 A Test of Wright and Vasquez on an American Population

Carrie B. LeGarde, MA*, 974 Auloa Road, Kailua, HI 96734

After attending this presentation, attendees will understand the applicability of the Wright and Vasquez equations for estimating maximum length of a long bone from fragmentary remains on an American sample.¹

This presentation will impact the forensic science community by providing another possible means of estimating maximum length of the tibia and fibula from fragmentary remains for the purpose of stature estimation on an American sample.

Obtaining a stature estimate is difficult when dealing with fragmentary remains since stature estimation models are most successful when maximum length measurements are utilized. Multiple studies have produced equations that estimate the maximum length of a long bone based on measurements of fragments or bone segments, which can then be used in stature estimation models. Currently, there are no methods for estimating maximum length of the fibula from fragments for an American population. Wright and Vasquez produced estimation equations for the fibula based on a Guatemalan sample, but suggested that before applying their equations to a different population, the equations should be validated on complete long bones from the population in question.¹ In response, this study utilizes measurements from the tibiae and fibulae of 19 American Korean War soldiers to test the applicability of Wright's and Vasquez's equations on an American population.

The regression equations using fibular segments produced by Wright and Vasquez were used to calculate the estimated maximum length of the fibula and tibia.¹ The estimated maximum lengths were then compared to the actual maximum length of the elements. When Wright and Vasquez tested their equations on a known Guatemalan population, the equations for estimating tibial length from segments of the fibula actually performed better than the equations utilizing segments of the tibia. For this reason, regression equations for segments of the tibia were also used to investigate if, indeed, the fragmented fibula is more reliable than the fragmented tibia for estimating maximum length of the tibia on an American sample as well.

This study shows that the Wright and Vasquez equations perform well on an American population. Following the procedure Wright and Vasquez used for testing their equations, the mean difference between estimated and actual maximum lengths was calculated, as well as Mean Absolute Deviation (MAD) and Mean Squared Error (MSE).¹ The probability for a paired t-test between estimated and measured lengths for each equation was also calculated. Wright and Vasquez considered only $p < 0.001$ to indicate significant differences between the estimated and actual lengths.¹

No tibial or fibular length estimates using the regression equations differed significantly from the actual maximum lengths as evidenced by no p values less than 0.001. The mean difference was 2mm or less for the majority of the equations. The equations with the greatest mean difference were the equations estimating tibial length from fibula segments, ranging from 2mm to 5.36mm. Overall, the MAD was relatively small for all equations and it was less than the standard error of the estimating equations in all cases. The tibial length was underestimated in all equations, reflected by a negative mean difference. The maximum length of the fibula was overestimated for two of the three equations. Estimating the maximum length of the tibia from incomplete fibulae did not perform as well as using tibial segments, but they still performed adequately.

The results of this analysis are promising for the applicability of this method on non-Guatemalan remains. Although the sample size is small, this study suggests that Wright's and Vasquez's equations for estimating maximum length of the tibia and fibula from fragmentary remains can be used on an American population.

Fragmentary Remains, Stature, Fibula

A24 **Bilateral Asymmetry in Age-Related Trait Expression of the Pubic Symphysis and Auricular Surface of the Ilium**

Kyle A. McCormick, MA*, 805 Deery Street, Knoxville, TN 37917; and Michael W. Kenyhercz, MS, University of Alaska Fairbanks, 403 Salcha Street, 310 Eielson Bldg, Fairbanks, AK 99775

The goal of this presentation is to inform attendees about the consistency in age-related trait expression between the left and right portions of two popular skeletal regions for age-at-death estimation — the pubic symphysis and the auricular surface of the ilium.

This presentation will impact the forensic science community by providing a more nuanced understanding of age-related changes to the aforementioned joint surfaces and how this possibly affects current age-at-death estimation methods.

Currently, there are two major types of methodology for age assessment from the pubic symphysis and auricular surface — phase- and component-based methods.¹⁻⁴ Lovejoy et al. and Brooks and Suchey presented phase-based methods for age estimation from the auricular surface and pubic symphysis, respectively.^{1,2} These methods are based on the gestalt of surface morphology, where traits are lumped together into phases. When present, both the left and right sides of these surfaces should be assessed. However, phase-based methods do not provide a means for incorporating information from both sides into a cohesive age estimate. This limitation is most obvious when left and right sides show differing morphologies. Component methods, on the other hand, score traits separately and each contributes independently to an age estimate. Buckberry and Chamberlain and Milner and Boldsen present component methods for the auricular surface and the auricular surface and pubic symphysis, respectively.^{3,4} Like phase-based methods, Buckberry and Chamberlain suggest that both left and right sides should be scored, but do not provide a framework for incorporating information from both sides into an age estimate. Only Milner and Boldsen provide a means for incorporating left and right scores into a single age estimate.⁴ The current study assesses asymmetry in trait expression of the left and right sides of the auricular surface and pubic symphysis to identify possible areas of uncertainty in age estimation.

The primary goal of the present study was to assess the agreement in left and right expression of three age-related traits of the pubic symphysis and five of the iliac auricular surface. The traits of the pubic bone are relief, texture, and margin morphology of the symphyseal surface. The traits of the auricular surface are transverse organization, microporosity, macroporosity, apical change, and retroauricular activity. These traits were scored on different locations of each surface (i.e., superior/inferior demiface) using a condensed scoring system based on Milner and Boldsen.⁴ The study sample consists of 97 American White males and females aged between 20 and 66 years from the William M. Bass Donated Skeletal Collection. Left and right agreement was assessed using the Intraclass Correlation Coefficient (ICC). A two-way random model was used, with agreement type 95% tolerance interval. The ICC was used over other agreement statistics because it also accounts for the variability in scores between observations or trait expressions of antimeres.

Overall, the pubic bone shows higher agreement than the auricular surface. Pubic symphysis ICC scores are moderate to strong (symphyseal relief = 0.65, texture = 0.46, and margin = 0.70). Auricular surface ICC scores are poor to moderate (for transverse organization = 0.33, microporosity 0.49, macroporosity = 0.51, and apical change = 0.32).

These results suggest that age-related traits progress differentially between left and right portions. This result is especially true for the auricular surface. Component methods that incorporate left and right trait scores into a single age estimate, such as Transition Analysis, are preferable over phase-based or component methods that do not incorporate left and right scores into a cohesive age estimate.

A25 A Validation Study of Sex Estimation From the Scapula and Clavicle in a Modern United States Population

Danna N. Bran, BA, 201 S Bradfield Avenue, Compton, CA 90221*

After attending this presentation, attendees will understand the applicability of a sex estimation technique developed on an archaeological collection in New Zealand in a modern context.

This presentation will impact the forensic science community by providing an applicable sexing technique with high accuracy for use in cases where the os coxae and cranium are not available or are poorly preserved.

In forensic anthropology, sex is one of the first attributes reviewed by forensic anthropologists.¹⁻⁶ Finding complete remains of an individual increases the chances of correct identification; however, frequently only incomplete remains are found. For this reason, new sex estimation methods and the validation of existing methods using various bones in the body are necessary.⁷⁻¹¹

The clavicle and scapula are comparable to the os coxae, sacrum, and coccyx, which form the pelvic girdle, the base that supports the appendicular skeleton of the lower half of the body. Because of a relatively high degree of sexual dimorphism in the human os coxae, more attention has been given to those elements in the development of new accurate methods for sex estimation. The pectoral girdle shows less obvious sexual dimorphism, but promising traits on the clavicle and scapula have been documented, with reportedly high degrees of accuracy.¹²

In this study, a technique developed by A.M.C. Murphy using an archaeological sample from New Zealand was tested on the William M. Bass Donated Skeletal Collection at the University of Tennessee.¹³ Sliding calipers were used to measure the diameters of the sternal and acromial end of the clavicle and height and breadth of the glenoid fossa of the scapula. Data were obtained from 125 females and 121 males during the current study. Only adult individuals with fused epiphyses were used and left elements were given preference to prevent potential inconsistencies in right-handed asymmetry. Furthermore, only individuals of White ancestry were measured due to their larger sample size within the collection. Discriminant function analysis was then applied through the use of the statistical program Statistical Package for the Social Sciences (SPSS) by IBM® to test Murphy's method.

Statistical analysis shows the discriminant function as statistically significant with a Wilk's lambda of 0.394 and significance level of .000, which indicates that the function can effectively discriminate between males and females with an accuracy rate better than chance. The coefficient with the greatest discriminating ability is glenoid breadth, and the least discriminating coefficient is sternal diameter. An 89.9% accuracy rate in estimating sex was reached with a sectioning point of 0.0205.

A second statistical analysis tested the accuracy of this function as it applies to younger age-at-death versus older age-at-death individuals. The researcher chose the differentiating point of 50 years of age. Discriminant function analysis was applied first to those less than 50 years old and then to those older than 50 years of age. The accuracy rate in correctly estimating sex increased for individuals less than 50 years old to 92.9% and for individuals older than 50 years of age to 90.7%.

Although the method applied to this modern United States population sample did not reach Murphy's 97.7% accuracy rate, this study will present an anthropological method that can be applied to current forensic cases involving unidentified individuals where other methods of identification are unattainable that portrays a statistically significant accuracy rate of 89.9% in correctly estimating sex.

A26 Classification of a Sample of Chinese Males From Cuba Using FORDISC® 3.1

Kaleigh C. Best, BA*, 218 Maiden Lane, Erie, PA 16504; Stephen D. Ousley, PhD, Dept of Applied Forensic Sciences, Dept of Anthropology, 501 E 38th Street, Erie, PA 16546; and Curtis W. Wienker, PhD, University of South Florida, Dept of Anthropology, SOC107, Tampa, FL 33620-8100

The goals of this presentation are to give attendees the opportunity to explore the variation present in the Chinese-Cuban sample and to understand how it compares to known modern and historic reference samples.

This presentation will impact the forensic science community by providing classification accuracies for a traditionally ill-represented, unique ancestral population using modern statistical techniques.

FORDISC® is a widely used tool for the estimation of ancestry based on a number of cranial measurements that differ between population groups. Cuba has a diverse genetic background that includes Native American, African, Spanish, and Chinese influences. Native American groups, decimated and enslaved by the Spanish, eventually dwindled to numbers that led to the importation of slaves from West Africa. After the banning of slavery in the late 1800s, Chinese were brought to the island as indentured servants and later middle-class Chinese businesspersons came to the island in the 1920s. These waves of migrants from three continents helped create the diverse Cuban population that is present today. Remains from a recent Chinese cemetery exhumed and now incorporated into the Aristides Mestre Laboratory of the Montané Anthropology Museum, University of Havana, Cuba, include 49 Chinese males, according to records. It is the goal of this project to investigate how this group classifies using FORDISC®.

Fourteen cranial measurements, as defined by standards, were collected for this study from the 49 Chinese-Cuban males. Individuals were then analyzed in FORDISC® 3.1 using the Forensic Data Bank (FDB) and Howells' groups in accordance with the procedures outlined in Ousley and Jantz.^{1,2} The posterior probabilities and typicality probabilities were then utilized in eliminating groups that did not meet acceptable cutoffs (posterior probabilities >0.1 and F-typicality >0.05). Classification accuracies were evaluated using leave-one-out cross-validation. Further analyses included comparing the Cuban male sample as a whole to forensic and Howells' groups using the Mahalanobis distance.

Using the FDB groups, individuals classified as Chinese 32.7% of the time and as an Asian group 63.3% of the time. A further breakdown of classifications of groups is: Vietnamese Male = 16.3%, Japanese Male = 14.2%, Guatemalan Male = 14.2%, Black Male = 8.2%, American Indian Male = 6.1%, and Hispanic Male = 2.0%. One individual classified as a Japanese female and two individuals could not be classified due to low typicality scores. The correct sex classification rate for the sample was 98%. When analyzed as a group using FORDISC®, the linear discriminant function classified 32.7% (16/49) of the sample into its own group when Basion-Prosthion Length (BPL) was removed due to the large number of the samples missing this measurement. Results demonstrate that the Wienker sample is closest to Asian groups, particularly the Chinese males, with a Mahalanobis distance of 2.5. Other close groups include the Vietnamese males with a Mahalanobis distance of 3.3, and the Japanese males with a Mahalanobis distance of 3.6. The Cuban-Chinese males were most similar to Howells' Chinese groups (Anyang and Hainan), followed by other East Asian groups.

In summary, classification results corroborated the recorded Chinese origins of the sample. Individuals from this sample classified as East Asian 63% of the time. Even when attributed to a single ancestry, the Chinese-Cubans classify as Chinese males 33% of the time, the highest classification rate of the groups compared. These classification percentages are better than random chance and thus indicate that a large component of the morphological variation reflects the group's geographic source. As a group, classifications of the sample using FDB and Howells' data reflect Southeast Asian affinities, particularly indicative of Chinese heritage. The comparative samples come from different areas in China and reflect different ethnic groups. The FORDISC® Chinese sample includes individuals from Hong Kong and the Howells' groups include the Anyang from northern China and the Hainan from southern China.

A27 Multi-Method Resolution of Small-Scale Commingling

Janet E. Finlayson, MA*, University of Florida, Turlington Hall, Rm 1112, PO Box 117305, Gainesville, FL 32611; Eric J. Bartelink, PhD, California State University, Chico, Dept of Anthropology, Butte 311, 400 W First Street, Chico, CA 95929-0400; Alexandra Perrone, MA, 2590 California Park Drive, Apt 13, Chico, CA 95928; and Kevin Dalton, MA, California State University, Chico, 400 W First Street, Chico, CA 95929-0400

The goal of this presentation is to highlight the use of a multi-method approach for resolving small-scale cases of commingled remains. After attending this presentation, attendees will understand the benefits of using portable X-ray fluorescence spectrometry in conjunction with traditional methods to resolve complex commingling cases.

This presentation will impact the forensic science community by highlighting the application of elemental analysis to resolve commingling in addition to the array of traditional methods in forensic anthropology.

Methods commonly used to sort commingled remains tend to rely on the presence of joint surface morphology, diagnostic anatomical features, osteometric sorting, or, more recently, the use of DNA analysis. Taphonomic conditions, such as carnivore scavenging, may inhibit the use of these techniques by fragmenting the remains, resulting in loss of diagnostic features and articular joint surfaces. In such instances, elemental analysis holds enormous potential. Previous research has established that portable X-Ray Fluorescence (pXRF) can be a useful tool for sorting small-scale commingling cases.¹⁻² This presentation focuses on a case study involving the successful use of traditional osteological methods, DNA analysis, and pXRF for resolving a case of commingling.

In 2012, an informant told law enforcement that he and three other Mexican nationals were involved in an illegal marijuana growing operation in northern California. The informant further indicated that one individual shot and killed two of the others while they were in the marijuana field. The informant and suspect then buried both decedents in two shallow graves at the location before fleeing to southern California. Law enforcement located the gravesite and, although buried, both individuals were heavily scavenged by large carnivores, most likely black bears. This resulted in significant commingling of the remains. Each set of human remains was assigned a unique barcode and geographic location at the scene and was then submitted to the California State University, Chico Human Identification Laboratory for analysis.

Several traditional sorting methods were employed, including: (1) reconstruction of fragmented remains through physical matching; (2) visual pair-matching of bilateral elements; (3) articulation to evaluate joint congruence; (4) osteometric sorting; (5) evaluation of taphonomic patterns; and, (6) DNA analysis. After applying these methods, a left radius, ulna, scapula, clavicle, a left and right humerus, a mandible, and several right-hand elements still could not be assigned to an individual. In several instances, carnivore scavenging damage or lack of diagnostic joint morphology inhibited the use of these techniques and pXRF was used to segregate the remains.

Following methods recently outlined in Perrone et al., 95% confidence intervals were established for seven chemical elements detected (silicon (Si), phosphorus (P), potassium (K), calcium (Ca), manganese (Mn), iron (Fe), and cobalt (Co)) based on skeletal remains previously assigned to Individual I and Individual II.² Elemental concentration values were consistent with the informant's statement that the remains represented two individuals. Results of the pXRF analyses also indicated that nearly all unassigned skeletal elements belonged to Individual I, whereas Individual II was only represented by two mandibular fragments.

In this case study, the use of pXRF combined with several traditional sorting methods permitted the resolution of commingling. In addition, the correct assignment of skeletal elements to each individual facilitated the assessment of the biological profiles, trauma analysis, and evaluation of taphonomic patterns. This multi-method approach resulted in the accurate sorting of skeletal elements and the subsequent repatriation of the remains to their respective families.

A28 The Optimized Summed Scored Attributes Method for the Classification of American Blacks and Whites: A Validation Study

Michael W. Kenyhercz, MS, University of Alaska Fairbanks, 403 Salcha Street, 310 Eielson Bldg, Fairbanks, AK 99775; Alexandra R. Klares, PhD, Mercyhurst University, Dept of Applied Forensic Sciences, 501 E 38th Street, Erie, PA 16546; Christopher W. Rainwater, MS, OCME, 520 1st Avenue, New York, NY 10016; and Sara M. Fredette, BS*, Mercyhurst University, Dept of Applied Forensic Sciences, 501 E 38th Street, Erie, PA 16546

After attending this presentation, attendees will understand the reliability of the Optimized Summed Score Attributes (OSSA) method created by Hefner and Ousley, which is currently employed in biological profile ancestry estimation for unknown individuals in active forensic cases.¹

This presentation will impact the forensic science community by proposing a new sectioning point that maximizes classification accuracy, thus demonstrating the utility of OSSA for modern forensic casework.

Ancestry estimation is essential for assessing the potential identity of unknown persons and is one of the most difficult parameters of the biological profile (age, sex, stature, ancestry) to estimate. Non-metric traits have been pervasive in their use within the field of forensic anthropology and are continually used in active cases and in research.² Recent work examining the “gestalt” approach to ancestry estimation shows that decisions by researchers concerning the population affinity of an individual may be established within seconds upon first viewing the crania.³ Thus, initial impressions, based upon past experiences, bias the researcher either consciously or subconsciously. The aforementioned impressions are generally the product of typological approach-based training and education, which have been ubiquitously taught in the foundation of forensic anthropology and are still included in many introductory forensic anthropology texts. As a means to standardize this typological approach, Hefner consolidated the various typological character lists used in forensic anthropology to 11 traits, either binary or expanded into ordinal character states, to more adequately capture the range of normal human variation observed and to avoid the inherently biased typological approach.⁴

Six of the original Hefner non-metric traits were incorporated by Hefner and Ousley into the OSSA method for classification of ancestry.^{1,4} The scores of each of the traits are then converted into a binary score and summed. Individuals with scores ≤ 3 are classified as Black (B) and ≥ 4 as White (W). The OSSA approach includes statistical measures of classification and a prediction plot for group membership. For the current research, these six traits were collected for 208 American Black ($n=101$) and White ($n=107$) crania from the Hamann-Todd Human (HTH) Osteological Collection, 28 positively identified Black ($n=5$) and White ($n=23$) crania from Mercyhurst University’s Department of Applied Forensic Sciences (DAFS) forensic cases, and 38 positively identified Black ($n=10$) and White ($n=28$) crania from the Office of the Chief Medical Examiner (OCME) in New York City. Ancestry was first determined using the cut-off scores (≤ 3 for Black and ≥ 4 for White) supplied by Hefner and Ousley.¹ The original sectioning point was chosen on the basis of maximizing correct classifications. Next, the cut-off score was heuristically adjusted to maximize classification accuracy for the current sample.

The HTH collection achieved a total correct classification of 68.3% (B=50.5%, W=85.0%) using the suggested OSSA sectioning point. Shifting the sectioning-point heuristically to ≤ 4 for Black, improved total correct classification of the HTH sample to 77.9% (B=80.2%, W=69.2%). The Mercyhurst sample had a total correct classification of 71.4% (B=20.0%; W=82.6%) using the suggested sectioning score and 89.3% (B=60.0%, W=95.7%) using the adjusted sectioning point of 4. The OCME sample showed a total correct classification of 89.5% (B=70%, W=96.4%) using the suggested sectioning score and 94.7% correctly classified (B=90.0%, W=96.4%) using the adjusted sectioning score of 4.

In the present study, classification accuracy improved in all three samples using the adjusted sectioning point of ≤ 4 for Black. American Blacks had higher classification accuracy than Whites in the HTH sample (using the adjusted cut-off), yet had lower correct classifications in the DAFS and OCME samples. Secular change may potentially explain these differences given the time disparity between the HTH sample and the two modern ones. It is suggested when examining modern, forensic cases to increase the cut-off score to 4 for best classification accuracy. Furthermore, practitioners should have adequate experience in scoring the traits as defined by Hefner and Ousley, as well as be sufficiently familiar with the normal range of human variation to confidently score each of the traits.¹

A29 **Vertebral Maturation in Age Estimation: Further Testing the Revised Method of Scoring the Timing and Progress of Epiphyseal Ring Union**

A. Midori Albert, PhD, University of NC Wilmington, Dept of Anthropology, 601 S College Road, Wilmington, NC 28403-5907; and Kate D. Sherwood, 10401 Litzinger Road, St. Louis, MO 63131*

After attending this presentation, attendees will gain a more in-depth understanding of the pattern, sequence, and timing of vertebral ring union for the cervical, thoracic, and lumbar vertebrae. The revised method of scoring epiphyseal ring union and the relationship with age-at-death was further explored on a known skeletal sample. Findings from this study may be used to corroborate information from other skeletal age indicators to more accurately estimate age-at-death in cases of unknown identity.

This presentation will impact the forensic science community by explaining how vertebral maturation correlates with age-at-death when using the revised method of scoring the progress of epiphyseal union of the superior and inferior vertebral centra (or “ring” epiphyses). Results of this study may potentially aid in the determination of skeletal age-at-death for pre-teenagers up through young adults which, when considered in conjunction with other skeletal age indicators, may improve the accuracy of age estimation in human identification.

The progress of union of the superior and inferior ring epiphyses of the vertebral centra was documented for the pre-sacral vertebral column, where applicable (i.e., C2 inferior, C3-C7, T1-T12, L1-L5) from a sample of 54 females and 38 males, ages 10 to 30 years at death, from the Lisbon Collection, National Museum of Natural History (Bocage Museum), Lisbon, Portugal.

Epiphyseal union was documented using the revised five-stage method: (1) Stage 0: no fusion, bare centrum; (2) Stage 1: partially fused ring, sections fused and unfused, gaps present; (3) Stage 2: complete fusion, clear demarcation between ring and centrum, no gaps but possibly a groove, no remodeling; (4) Stage 3: complete fusion, ring edges are melded with centrum, a slight groove may be seen in some areas but centrum is fully remodeled in other areas; and, (5) Stage 4: complete fusion, ring edges are melded with centrum, bone is remodeled with no grooves. This modified five-stage scoring method focuses on the distinction between differing appearances of complete union, mainly where complete union may present with or without a groove, indicating that remodeling has not or has occurred.

Spearman’s rank correlation coefficients indicated a relatively high positive (and significant, $p < 0.05$) relationship between vertebral ring union mean values and age at death, $r_s = 0.90$. High positive and significant ($p < 0.05$) correlations were also found when each vertebra type was analyzed distinctly (i.e., cervical, thoracic, and lumbar), for sexes combined, and for the female and male samples separately, ranging from $r_s = 0.84-0.92$.

The sample was then divided into five age groups, sexes combined, to gauge the progression of union: (1) Group 1: 10 to 13 years of age; (2) Group 2: 14 to 17 years of age; (3) Group 3: 19 to 21 years of age; (4) Group 4: 22 to 25 years of age; and, (5) Group 5: 26 to 30 years of age. Analysis of Variance (ANOVA) and most paired samples t-test results showed no significant differences in vertebral ring union mean values between age groups, with sexes combined and when sexes were tested separately, which could be an effect of small sample sizes. Noteworthy were the raw data observations that provided insights into the subtle patterns and progression of vertebral ring union. Specifically, union began as early as 11 years of age in both females and males for each vertebra type — this is earlier than previously shown; prior samples did not include many individuals as young as 10 years of age. Union was complete in all vertebrae (all vertebrae Stage 3 or 4) at 18 years of age for females and 21 years of age for males. Stage 3 persisted up through 30 years of age in both sexes. Stage 4, complete union with remodeling, was first evident in females at 18 years of age for all vertebra types and for males at 20, 21, and 17 years of age for cervical, thoracic, and lumbar vertebrae, respectively.

Findings from this study may be used to either support information from other skeletal age indicators or provide a general guideline for estimating age-at-death if only vertebrae are recovered in forensic cases.

Vertebral Maturation, Epiphyseal Union, Age Estimation

A30 Reliability of Craniometric Measurements Using a Variety of Imaging Technologies

Adam H. Richard, MA*, FBI Laboratory, 2501 Investigation Parkway, Quantico, VA 22135; Connie L. Parks, MA, 2501 Investigation Parkway, Laboratory Division, Quantico, VA 22191; and Keith L. Monson, PhD, 2501 Investigation Parkway, Quantico, VA 22135

After attending this presentation, attendees will understand that measurements taken from representations of crania are, for the most part, just as reliable as those taken directly on the crania themselves. Attendees will also learn which measurements should be used with caution for each tested data format and how to mitigate these issues when collecting data.

This presentation will impact the forensic science community by supporting the validity of expanding anthropological osteometric databanks to include information derived from indirect sources such as medical scans or laser scans. The ability to reliably collect skeletal information from these indirect sources will greatly enhance the potential for collecting osteometric data on currently underrepresented demographic groups.

With the continuing advancement of biomedical imaging and 3D modeling technologies, anthropologists have begun making use of indirect osteometric data derived from scans of skeletal elements. In response to this trend, a study was undertaken to test the reliability across several different imaging technologies of 26 standard craniometric measurements frequently used in forensic casework.¹ Measurements from five crania of known individuals were collected in duplicate by two anthropologists from Computed Tomography (CT) scans and 3D laser scans of the original crania. The laser scans were also used to create prototype models of the original crania. These prototypes were subsequently laser-scanned and measurements were collected from the prototypes and the laser scans of the prototypes.

Craniometric data were initially evaluated for inter-observer and intra-observer error, with one measurement (Bimaxillary (inferior malar) breadth (ZMB)) showing significant inter-observer error. The nature of this error was identified and a second round of measurement collection was undertaken, this time eliminating any inter-observer error. Measurement sets from each technology were then compared with one another using the previously collected osteometric measurements taken on the crania themselves as the ground truth. Statistical analyses conducted on the craniometric data included repeated measures Analysis of Variance (ANOVA), as well as total technical error of measurement and percent total technical error of measurement.

Results show that the majority of measurements demonstrated no significant differences across data formats. However, a few select measurements were found to be problematic for particular technologies. For example, measurements taken from CT scans in a supero-inferior direction (e.g., Basion-Bregma Height (BBH), Orbital Height (OBH)) were prone to greater deviation from direct measurements of the cranium than other technologies, especially for CT scans taken at greater slice increment and thickness. Also, several measurements defined by Type 1 landmarks, particularly those occurring at complex or unclear suture junctures (e.g., Biasterionic (maximum occipital) Breadth (ASB), ZMB), were found to have high variance across all technologies while measurements based on Type 3 landmarks proved to be highly reproducible. This is contrary to measurements taken directly on crania, where measures defined by Type 1 landmarks are typically the most reliable. This observation is most pragmatically explained by the reduction or complete loss of suture definition in the scan data.

If alternative data sources are to be increasingly utilized for the collection of osteometrics, it is vitally important that efforts are made to ensure scanning parameters are sufficient to capture the level of detail required for accurate measurement collection. If measurements are to be collected from pre-existing scans, then a detailed understanding of how individual measurements may be impacted by the particular data format being utilized is necessary to avoid the introduction of unseen error and the possibility of drawing erroneous conclusions.

A31 Living Body Mass Estimation From Skeletal Elements in Forensic Contexts

Tyler E. Dunn*, 622 W Clark Street, Unit 3, Campaign, IL 61820

After attending this presentation, attendees will have an understanding of the possible place for body mass estimation in the anthropological biological profile.

This presentation will impact the forensic science community by showing the need to develop new inclusions into the biological profile and to statistically validate novel methods.

Body mass estimation in forensic anthropological contexts has the ability to augment the biological profile by providing information about an additional individualizing characteristic. Methods for estimation of body mass from skeletal elements are common in paleoanthropological and bioarchaeological populations; however, these methods have not been thoroughly tested in modern individuals of known body mass. Despite research on this topic in other bioanthropological contexts, methodological and statistical support for the inclusion of body mass in the traditional biological profile is lacking in the forensic literature. The limited populations on which these estimation equations are based may further limit the forensic applicability of these methods.

Across biological anthropology, body mass estimates are usually calculated from femoral head diameter and bi-iliac breadth. In the case of the femur, a mechanical approach is applied and relies on the idea that a bone will respond and remodel to the forces that the bone undergoes; in this case, the weight force of the individual. The estimation of body mass from bi-iliac breadth relies on the morphometric relationship between volume, density, and weight. The body is conceptualized as a cylinder. In order to estimate the volume of a cylinder, the diameter is needed; in this case, the analogous diameter of the human body is the bi-iliac breadth of the pelvis.

This study compares two commonly used methods for body mass estimation in a documented sample drawn from the William M. Bass Donated Skeletal Collection (n=388) consisting of 154 females and 233 males. The mean age-at-death of the sample was 62. All individuals in the sample are of known forensic body mass which ranged from 36.3kg to 190.5kg. Forensic body mass relies on self-reporting, reporting by next-of-kin, or is ascertained from medical and/or governmental paperwork. Although forensic body mass has inherent biases, forensic body mass is a similar measure to the body mass used in medicolegal death investigations by law enforcement.

Results indicate that the methods of body mass estimation from osteometric distances compare well throughout the range of body masses in the sample. Despite this correlation, osteometric dimensions were poor predictors of forensic body mass in individuals whose body masses were considered underweight or obese ($p>0.05$). The middle ranges of body mass had no statistical difference between the skeletal indicators and the forensic body mass ($p<0.05$). Both of the estimates of body mass from osteometric distances limit the variation in the estimates. When compared to the forensic body mass, both of the osteometric methods artificially skew the estimates toward a central mean while the variation in the forensic body mass is greater and therefore the distribution is wider. The standard deviation for the body mass estimations from the femoral head diameter and bi-iliac breadth are 8.18kg and 7.76kg, respectively, while the forensic body mass has a larger standard deviation of 25.44kg.

Although there is some reliability in the estimation of body mass from skeletal metrics, the use of these methods in modern forensic contexts is cautioned as the range of modern body mass variation could be much greater than in the archaeological populations on which the estimation equations are based. Although the theoretical framework for the estimation of body mass from skeletal elements is accepted in some bioanthropological contexts, the wide variation of body mass that is unique to modern populations confounds forensic applications. Better techniques to estimate body mass from the outliers of the body mass spectrum are needed in order allow its inclusion in forensic contexts.

Body Mass, Biological Profile, Validation

A32 Skeletal Indicators of Shark Feeding on Human Remains: A Case Study From the Eastern Coast of Florida

Michala K.S. Schaye*, 1376 Mowry Road, Rm G-17, Gainesville, FL 32610; Allysha P. Winburn, MA, C.A. Pound Identification Lab, Cancer/Genetics Research Center, 2033 Mowry Road, Gainesville, FL 32610; and George H. Burgess, MS, Florida Museum of Natural History, University of Florida, Gainesville, FL 32610

After attending this presentation, attendees will gain an understanding of skeletal trauma/damage patterns that likely indicate shark predation and/or scavenging through the examination of a case study originating from the C.A. Pound Human Identification Laboratory (CAPHIL) at the University of Florida (UF).

This presentation will impact the forensic science community by contributing to current forensic anthropological research regarding trauma and taphonomic analyses from skeletal elements deposited in a maritime environment — in particular, remains that were subjected to shark predation and/or scavenging. Furthermore, the benefit and utility of collaborating with experts in shark biology and cases of shark attacks will be discussed.

Shark predation and scavenging are becoming increasingly prevalent, especially along the United States' coastlines. Extended postmortem intervals and taphonomic damage from factors such as sand sediment and wave action in the marine depositional environment may obscure potential indicators of trauma and/or postmortem damage from shark feeding activities. A case study from the CAPHIL is presented in which three disparate human skeletal elements (left and right ossa coxae and a right proximal femur) washed ashore within several miles of each other on Florida's eastern coastline. Forensic anthropologists at the CAPHIL putatively reassociated these elements based on pair matching, articulation, and similar biological profile indicators (i.e., age and sex), in addition to the elements' similar taphonomic signatures indicative of deposition in a maritime environment (e.g., sandy adhesions, small barnacles, and erosion characteristic of wave action).

All three elements evidenced a distinctive pattern of trauma or damage, including sharp force defects and torsional loading. Anteroposterior loading on both ossa coxae resulted in bone failure around the acetabula, while a spiral fracture completely transected the right femur, of which only the proximal portion was recovered. During a collaborative analysis process with personnel from the Florida Program for Shark Research at UF's Florida Museum of Natural History (FLMNH), CAPHIL and FLMNH analysts determined that the pattern of damage to the bones likely resulted from shark predation or scavenging. Analysts applied the suite of traits indicative of shark-inflicted trauma described by Allaire et al., and determined that several of these traits were present on the remains — among them a set of parallel, incised bone gouges resulting from the spiraling action of a shark's teeth along the femoral shaft.¹ No teeth were retained in the sharp force defects, precluding a definitive diagnosis of shark species; however, based on the geographical location of the remains' discovery, the size and patterning of the shark-inflicted sharp-force damage, and the high torsional forces required to produce the damage, shark researchers from the FLMNH estimated that this distinctive pattern of trauma/damage was likely created by a bull or a tiger shark. It should be noted that analysts were unable to determine whether this shark activity constituted predation or scavenging, as all trauma/damage to the bone occurred while the bone was in a fresh or otherwise hydrated state.

This case study applies previous research on shark predation/scavenging to a case from the Florida coast with a distinctive taphonomic signature. It highlights the importance of communication and collaboration — not only within a single forensic anthropology laboratory but, perhaps even more importantly, with researchers from outside fields whose expertise may provide valuable insight into analyses of skeletal trauma and taphonomy.

Anthropology Section - 2015

A33 A Protocol for the Collection and Culture of Microbes From the External Surfaces of Human Bone

Ashlee R. Griffin, BS*, JPAC Central Identification Laboratory, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853-5530

After attending this presentation, attendees will understand the techniques used to collect microbial samples from the external surfaces of human bone and how to culture and isolate these microorganisms to identify potential links between microbes and their bioerosion of bone. Histological studies of human bone show microstructural changes that have occurred postmortem. While the exact mechanisms behind these structural changes are unknown, they are likely to be microbially mediated changes.

This presentation will impact the forensic science community by contributing to the increased awareness of the microbially mediated changes that continue to occur in skeletal remains during the extended postmortem interval. By standardizing microbial collections from human bone, a higher potential number of living microbial species can be collected and studied for their role in bone taphonomy and bioerosion.

A common misconception is that the process of decomposition is complete once human remains become skeletonized; however, bone continues to be altered through diagenesis and micro-bioerosion. By having the ability to successfully collect and culture microbes from the external surfaces of human bones, a better understanding of the biological decomposition of bone can be achieved. Additionally, this protocol will allow for the identification of microbes associated with the extended postmortem interval, which may aid in determining time-since-death in skeletonized remains.

This protocol outlines the methods and materials used during the collection of samples from six different sets of Korean War skeletal remains disinterred from the National Memorial Cemetery of the Pacific (NMCP) in Honolulu, HI. These remains have been buried at NMCP since the late 1950s and were being disinterred for identification purposes.

Once the remains were removed from their caskets, one long bone from each set of remains was selected for sampling. The bones were dry-cleaned to remove any debris that may have been present on the bones. Sterile water and cotton swabs were used to swab each long bone and multiple samples were taken from each bone. The swabs were then streaked onto a standard nutrient agar plate and placed in an incubator at 22°C to allow microbial growth. After five to seven days of growth, bacterial isolations were conducted in order to more accurately identify each strain. The isolations were repeated for several more generations until one strain of bacteria was present per plate. Plates were selected for species identification by visually selecting different colonies for each set of remains. Colonies were identified via Matrix Assisted Laser Desorption/Ionization Time-of-Flight (MALDI/TOF). From the sampled remains, 12 different species of bacteria and fungi were identified. Species included *Proteus mirabilis*, *Providencia rettgeri*, and *Bacillus thuringiensis*, which have all been observed in decomposition studies. These results show that with this relatively simple protocol, it is possible to culture and identify microorganisms present on bone, allowing investigation of the changing microbial population involved in human decomposition during the extended postmortem interval.

Histology, Bacteria, Postmortem Microbiology

A34 A Comparative Analysis of Macroscopic, Microscopic, and Chemical Alterations in Modern and Ancient Bones: A Preliminary Study

Valentina Caruso, BSc, LABANOF, V. Mangiagalli, 37, Milan 20133, ITALY; Giorgio Caudullo, MA, LABANOF, V. Mangiagalli, 37, Milan 20133, ITALY; Valentina Scarpulla, BSc, LABANOF, V. Mangiagalli, 37, Milan 20133, ITALY; Emanuela Maderna, BSc, LABANOF, Laboratorio di Antropologia e Odontologia, Via Luigi Mangiagalli 37, Milano 20133, ITALY; Annalisa Cappella, BS, Via Mangiagalli 37, Milano 20133, ITALY; Emanuela Sguazza, BSc, LABANOF, Dipartimento di Scienze, Biomediche per la Salute, Milan 20133, ITALY; Debora Mazzarelli, BS, LABANOF-Sezione di Medicina Legale, Dipartimento di Scienze Biomediche per la Salute, V. Mangiagalli, 37, Milan 20133, ITALY; Alberto Amadasi, Via Mangiagalli 37, Milano 20133, ITALY; Luca Trombino, Università degli Studi di Milano, Milan 20133, ITALY; and Cristina Cattaneo, PhD, Universta Degli Studi Di Milano, Milan 20133, ITALY*

After attending this presentation, attendees will understand that the taphonomical evaluation of skeletal remains cannot be limited to the macroscopic aspect but must take into account microscopic and chemical alterations since these may react differently.

This presentation will impact the forensic science community by showing how information related to site of deposition, time-since-death, etc., should be searched not only macroscopically but also microscopically and chemically since different levels of tissue structure may tell different stories.

Bone conservation may be different according to the level at which one examines it: macroscopic, microscopic, chemical, or biochemical. Degradation can be used in relation to Postmortem Interval (PMI), environment of deposition of human remains, or applicability of biological tests. For this reason, it is fundamental to verify how, when, and in which components bone degrades. For example, is a well-preserved bone surface a predictor of the survival of the histological component? Or does a negative luminol test necessarily mean that the collagen in the bone is completely gone? Very few comparative studies exist in the literature. This study, therefore, has a dual goal: (1) investigating the preservation of the organic and inorganic bone components; and, (2) testing the accuracy and precision of the methods already employed.

The right tibia or femur of 40 human skeletons was collected from four known populations of the following historical periods: (1) ten Roman (3rd-5th century A.D.); (2) ten 16th century A.D.; (3) ten 17th century A.D.; and (4) ten contemporary (1990-1992 A.D.). Macroscopic, microscopic, and luminol testing were performed on all.

For the macroscopic analysis, this study evaluated the general appearance of the remains and their state of preservation, in accordance with Behrensmeyer's classification, through the observation of specific parameters and morphological characteristics.

Histological analysis was performed both on undecalcified and decalcified sections. The histological analysis conducted on the thin undecalcified sections was performed by scoring preservation according to the Oxford Histological Index (OHI). In parallel, the decalcified stained sections were scored as either well or badly preserved according to the percentage of collagen (>60%=well preserved).

To evaluate the survival of the heme molecule in bone, this study performed a luminol test, a quick, inexpensive method developed to detect blood traces.¹ As expected, results showed a divide in conservation between contemporary and archaeological bone. However, interesting results were seen when comparing different levels of preservation. The macroscopic evaluation showed that 62.5% of both contemporary and archaeological samples were well preserved (stage 0-1). Undecalcified histological microscopy in general showed a good osteonic conservation in contemporary (80%) bone, with high OHI (4-5), whereas archaeological bone showed a high OHI in only 20% of the samples. Therefore, a large difference was noticed in macroscopic and microscopic degradation, particularly among older bone.

When evaluating survival of the collagen component of bone via Hematoxylin-Eosin (H&E) microscopy of the decalcified bone, a slight amelioration in conservation was noticed, which may indicate that if the structure of the calcified matrix is degraded, the respective connective tissue component may be better preserved.

The luminol test was negative in 70% of the ancient samples and in 20% of the contemporary samples, as could be expected; however, when comparing the luminol vs. histological response among older samples, in 27% of cases where luminol was negative, microscopic preservation was very good, and in 25% of cases where histology was negative, luminol was positive.

In conclusion, results show that macroscopic, microscopic, and chemical preservation may not depend upon each other. This means that, according to the type of environment and to other unknown variables, the evaluation of taphonomical degradation must be performed at different levels.

A35 A Comparative Study of Human Decomposition Research Facilities in the United States: The Role of “Body Farms” in Forensic Applications

Nicole S. Klein, MA, 2935 Alaska Street, Baton Rouge, LA 70802*

After attending this presentation, attendees will understand the importance of human decomposition research facilities as well as the perceptions associated with them, within the forensic community as a whole.

This presentation will impact the forensic science community by providing, for the first time, an all-encompassing look at how human decomposition facilities are started, what they are used for, how their utilization may have changed since their inception, and what their role is in the future of forensic anthropology. This overview will in turn open up dialogue so the benefits of these facilities may be fully realized by the forensic science community, scholars, and the public as a whole.

The first human decomposition facility, the University of Tennessee’s Anthropological Research Facility, or the “Body Farm,” as it is more commonly known, was established in 1980. Not until 2006 did another of its kind open and in the past six years, the number of such facilities has tripled. Human decomposition facilities, and their amenities, are being used for research purposes more frequently each year, although there is little in the literature that describes the facilities themselves.

Interviews with facility representatives were used to gather data in order to better understand how these facilities are initiated, the difficulties and successes that come with such a facility, and their uses beyond decomposition research. Also, surveys were distributed to forensic professionals (including physical anthropologists) in the American Academy of Forensic Sciences and to university students to understand perceptions on the utilization and usefulness of human decomposition facilities and what place they have in the future of forensic sciences.

Results show that the majority of those involved in the forensic sciences, and especially forensic anthropology, find that human decomposition facilities provide vital research opportunities. Based on both interview and survey responses, more human decomposition facilities should be established in unique climate regions, in order to better understand decomposition rates. Also, individuals affiliated with facilities that are already established intend to continue collaboration with one another, to extend research opportunities to other departments and universities, and to expand their own research goals. Finally, the perceptions of non-forensic professionals (as represented by university students) regarding both human decomposition facilities and the role of forensic anthropology appear to be influenced by the popular media.

In order to realize the full potential of these facilities, their representatives and others who utilize them must continue to provide factual information and publishable material to counter misconceptions that are so readily provided by media culture. The human decomposition facility provides a unique opportunity for research, training purposes, and hands-on experience for all who use them. Their continuation is vital to better understanding taphonomic changes, thereby assisting in a medicolegal context.

Human Decomposition, Body Farms, Forensic Anthropology

A36 A Look Into the Past, Present, and Future of Decomposition Research and the Estimation of the Postmortem Interval

Nicholas V. Passalacqua, PhD*, JPAC-CIL, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853; and Mary S. Megyesi, PhD, JPAC-CIL, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853

The goal of this presentation is discuss the nature and trends of decomposition research in relation to the estimation of the Postmortem Interval (PMI) and to make recommendations for future research directions.

This presentation will impact the forensic science community by demonstrating that a great deal of decomposition research is unsystematic, descriptive, and/or idiosyncratic to a particular region. Statistically testable methods based on human subjects using depositional environments likely to be encountered in human remains cases are not particularly common.

The progression and rate of decomposition plays a key role in establishing a PMI for a set of human remains. The goal of this project is to examine previously published human and non-human decomposition research in relation to the estimate of the PMI in order to evaluate the scientific progress of past methods and projects and to make recommendations for future research directions.

In order to evaluate previous decomposition research, this study examined the American Academy of Forensic Sciences (AAFS) *Proceedings* from 2002 to 2014, as well as all issues of the *Journal of Forensic Sciences (JFS)* from 1972 to 2014. All research that examined decomposition was categorized and those projects which addressed issues of decomposition rates, progression, or other topics related to the estimation of PMI involving the usage of tissue or remains were included in the study sample (excluding those that were purely entomological in nature).

A total of 76 AAFS presentations and 77 papers published in the *Journal of Forensic Sciences* were examined for this project as they were determined to contribute to the literature on tissue decomposition and the estimation of the PMI. Overall, 32% and 45% of decomposition research involved human cadavers or tissue from the *JFS* and the AAFS *Proceedings*, respectively. Most studies (over 60%) either described decomposition in unique circumstances (e.g., corpses hanging or encased in concrete) or were descriptive decomposition studies for a region/area. Less than 20% of studies actually presented or tested a statistical method for estimating the PMI for a test of remains (not just describing time to reach a decomposition stage). Concerning non-human decomposition research, over 75% of the projects used pigs as proxies for human cadavers.

The discipline of forensic anthropology is currently in an era of method validation and refinement, much of which has been inspired by the *Daubert* criteria. This professionalization of the field has only been furthered by the introduction of best practice guidelines from the Scientific Working Group for Forensic Anthropology (SWGANTH); however, from this study, very few systematic approaches to decomposition research were found, and almost no statistical methods for estimating the postmortem interval of forensic cases (which should be the goal). Further, while soft tissue has been demonstrated to decompose similarly across a variety of species, no studies have directly correlated porcine specimens as reasonable proxies for human cadavers.¹ Looking toward the future, it is suggested that decomposition research focus on more defined, applicable approaches to the estimation of the PMI. There is a need to standardize variable collection and measurement for consistency between research projects (e.g., using accumulated degree days, consistent measures of total body score). Additionally, little research has been conducted on the decomposition of osseous materials for extended PMIs.²

Finally, this study contends that while non-human models were necessary proxies for foundational decomposition research, it is time to move on to systematic, directly applicable research using human cadavers to inform measurements of uncertainty for human forensic cases (which should be best practice). There are currently five human decomposition facilities and plans for at least two more in the very near future. With increasing access to human decomposition facilities and the questionable correlation of non-human to human decomposition models, the necessity of non-human decomposition research is called into question. Beyond entomological work, careful consideration of equating non-human and human decomposition studies is suggested and researchers without access to human subjects are encouraged to carefully evaluate how differences between human and non-human decomposition could affect results.³

Decomposition, Postmortem Interval, Time-Since-Death

A37 Inter-Observer Reliability of the Total Body Score System for Quantifying Human Decomposition

Gretchen R. Dabbs, PhD*, Southern Illinois University, Dept of Anthropology, 1000 Faner Drive, MC 4502, Carbondale, IL 62901; Melissa A. Connor, PhD, Colorado Mesa University, 406 Lowell Heiny Hall, 1100 N Avenue, Grand Junction, CO 81501-3122; and Joan A. Bytheway, PhD, Sam Houston State University, College of Criminal Justice, Box 2296, Huntsville, TX 77341-2296

The goals of this presentation are to: (1) demonstrate inter-observer reliability of the Total Body Score (TBS) system for quantifying decomposition; (2) illustrate where discordance between observers occurs; and, (3) make suggestions to improve the system.¹

This presentation will impact the forensic science community by demonstrating that the TBS system has low levels of inter-observer error and is a reliable method of quantifying decomposition.

Megyesi and colleagues' TBS system for quantifying decomposition is often cited and is currently used, along with other methods, to record decomposition at several human decomposition research facilities. However, the consistency of observations between two or more observers has never been tested. The use of multiple observers throughout the decomposition process is common at decomposition research facilities. Testing methods to determine rates and potential sources of error are now required in forensic sciences in this post-*Daubert* and National Research Council (NRC) report climate.^{2,3} This presentation addresses the observed deficiency.

Sixteen participants scored 59 observation packets using the Megyesi et al. system. The participants included both sexes ranging in education (undergraduate to PhD) and experience (0-6 months to 10+ years). All had some experience working at a human decomposition research facility and using the TBS system. The packets used 13 human cadavers in different stages of decomposition (Postmortem Interval (PMI) 2-186 days) from three human decomposition research facilities. The distribution of the PMI matched the outdoor sample of the original study as closely as possible. Each packet included photographs (averaging nine per packet) that minimally showed the overall body and close-up shots of the head/neck, trunk, and limbs. Where available, notes by the original on-site observer were supplied. Observers were provided the scoring tables from Megyesi et al.'s publication and instructed to follow only those descriptions, disregarding any modifications in use by individual facilities, and to return categorical scores for each bodily area (head/neck, trunk, and limbs), as well as overall TBS scores. When decomposition fit into more than one category, observers recorded both categories and averaged the contribution to TBS, as instructed by the original publication. Data analysis used a two-way random model Intraclass Correlation Coefficient (ICC) in Statistical Package for the Social Sciences (SPSS) (v. 17.0). The ICC is similar but deemed superior to a weighted Cohen's kappa.^{4,5}

The TBS method shows "almost perfect" agreement between observers.⁶ The overall single measure for Absolute Correlation Coefficient (ACC) is 0.859 for TBS and the Consistency Correlation Coefficient (CCC) is 0.878 for TBS. Assessment of the individual component categories shows variation in the correlation coefficients for each category, with head/neck being the highest (ACC=0.857; CCC=0.875), followed by the limbs (ACC=0.803; CCC=0.817), then trunk (ACC=0.690; CCC=0.720 — only "substantial agreement"). Education impacted the reliability, with individuals holding Master of Arts/Master of Science (MA/MS) degrees (ACC=0.989; CCC=0.923; n=8) or Doctor of Philosophy (PhD) degrees (ACC=0.896; CCC=0.940; n=2) having higher correlation coefficients than those with a Bachelor of Arts (BA) degree or less (ACC=0.801; CCC=0.841; n=6), although all education levels still fall in nearly perfect agreement. No difference in absolute or consistency correlations were observed when the participant sample was divided by experience, with the separation point being more or less than two years of experience (n=8, 8). The individual component scores followed similar patterns as the TBS score when examined under the filter of both education and experience.

Overall, trunk scores were the least concordant. Comments made by observers suggest this may result from difficulty identifying post-bloat release, greater variety of observed color change than described in the TBS system, and differences in decomposition of the upper (ribs) versus lower (abdomen) trunk. Common errors observed during data collation included simple issues, including use of non-existent categories for a particular body portion, probably the result of using the wrong table to make observations; recording point values for the category value (for example, C7 instead of C2, where 7 is the number of TBS points for category C2); and arithmetic errors in calculating TBS. All are easy to remedy (although the second problem could be difficult to parse for earlier stages of decomposition, where the categorical score and TBS point value are similar).

Thus, the TBS system is reliable, with near-perfect agreement between observers. Minor variation exists between observers based on education levels. The trunk category has the lowest level of agreement between observers and may provide an opportunity for improvement.

Inter-Observer Error, TBS, Forensic Anthropology

A38 An Innovative Analysis of the Postmortem Interval and Its Role in Juvenile Decomposition

Amanda R. Hale, MA*, 1326 Courtland Drive, Raleigh, NC 27604; and Ann H. Ross, PhD, North Carolina State University, Sociology & Anthropology, Campus Box 8107, Raleigh, NC 27695-8107

After attending this presentation, attendees will understand the importance of taphonomic processes in regard to juvenile and infant postmortem interval estimation.

This presentation will impact the forensic science community by presenting a novel statistical technique that can identify key decompositional changes in days that can be used as predictors for time-since-death in juvenile and infant remains.

Eight *Sus scrofa* (three juvenile and five fetal) remains were obtained fresh from the North Carolina State University (NCSU) swine farm in the summer, fall, and winter months of 2013. The initial day of deposition was determined by the traditional calendar for the start of each season. The three juvenile remains that analyzed were all placed on the surface. Each season two fetal pigs were deposited, one wrapped in a cotton blanket and one placed in a plastic garbage bag. The winter season does not contain bagged fetal data due to scavenging. All remains were enclosed in cages to prevent scavenging. Decompositional observations were quantified using Megyesi et al. to obtain a Total Body Score (TBS) and Anderson and VanLaerhoven decompositional stages were used for comparison.^{1,2} Fly activity was recorded as adults present, eggs present, larvae present, many larvae present, and none. Accumulated Degree Days (ADD) were calculated from daily maximum temperature with data obtained from the State Climate Office of North Carolina Lake Wheeler Road Field Lab weather station located one-half mile from the open-air site.

Statistical analyses were performed using a time series analysis that accounts for time between observations that can identify significant changes in quantified observations. The time series analysis utilizes an Autoregressive Integrated Moving Average (ARIMA) that incorporates a longitudinal mixed-effects model. The surface juvenile remains showed a significant seasonal pattern in days for decomposition with the summer juvenile reaching a TBS of 26 in eight days ($p\text{-value}=0.0001$), the fall juvenile reaching a TBS of 28 in 11 days ($p\text{-value}=0.0006$), and the winter juvenile reaching a TBS of 27 in 79 days ($p\text{-value}=0.0090$). These TBS values correspond with more than half the remains being skeletonized. The variables analyzed showed significant associations between TBS and ADD for summer, fall, and winter ($p\text{-values}=0.0023$, 0.0030 , and 0.0022 , respectively). Fly activity was only significant for the summer and fall months ($p\text{-values}=0.0046$, 0.0345 , respectively); however, there were no significant associations between the TBS and Anderson and VanLaerhoven decompositional stages.

The blanket fetal remains showed significant seasonal changes that mirror those seen in the juvenile remains. The summer fetal remains reached a TBS of 27 in seven days ($p\text{-value}=0.0001$), in the fall they reached a TBS of 29 in ten days ($p\text{-value}=0.0004$), and in the winter they reached a TBS of 27 in 79 days ($p\text{-value}=0.0001$). The variables analyzed showed significant associations between TBS and ADD for summer, fall, and winter ($p\text{-values}=0.0023$, 0.0300 , and 0.0024 , respectively). Fly activity and Anderson and VanLaerhoven stages were not found to be significant for any of the blanket fetal remains. The bagged fetal remains for summer and fall showed a similar decomposition patterns not related to seasonal deposition with the summer bagged fetal remains reaching a TBS of 26 in nine days ($p\text{-value}=0.0004$), and in the fall reaching a TBS of 27 in six days ($p\text{-value}=0.0001$). While the Anderson and VanLaerhoven stages did not have a significant association with TBS, fly activity did show a significant association with TBS for the fall bagged fetal remains ($p\text{-value}=0.0231$). This may account for the advanced rate of decomposition relative to the summer period.

The results of this study further support the importance of seasonal and burial deposition on the rate of decomposition. The implications that fly activity are of less significance than temperature should be explored and may relate to access to remains. This study also illustrates that more comprehensive stages of decomposition need to be investigated. Multi-environmental approaches in combination with time series analysis in experimental studies may provide predictive power for estimating the postmortem interval in medicolegal contexts.

This project was supported by a National Institute of Justice grant (2012-DN-BX-K049).

A39 Human Identification From Burnt Remains

Joe Adserias, DDS, PhD*, C/ Balmes 62, Barcelona, SPAIN; Anna Hospital, MD, Figueres, Girona 08007, SPAIN; Luis L. Cabo, MS, Dept of Applied Forensic Sciences, 501 E 38th Street, Erie, PA 16546; Steven A. Symes, PhD, Mercyhurst College, Mercyhurst Archaeological Institute, 501 E 38th, Erie, PA 16546; and Dennis C. Dirkmaat, PhD, Mercyhurst University, Dept of Applied Forensic Sciences, 501 E 38th Street, Erie, PA 16546

After attending this presentation, attendees will acquire a deeper understanding of the cremation process as well as of some alterations of human bone and teeth commonly associated with fire exposure.

This presentation will impact the forensic science community by describing the skeletal traits observed after a commercial cremation that can be used to estimate the biological profile as well as to achieve an individual identification.

Cremation of biological materials is a destructive and minimizing process. Burnt human remains identification is challenging at best. The most common methods for identification of burnt remains are odontology and DNA. However, these methods require the availability of antemortem records to be compared to postmortem data. In cases where no antemortem records are available, the first step in the identification process is to determine a biological profile of the victim through the assessment of sex, ancestry, age, and stature. Next, antemortem trauma or other pathology markers, particularly in radiographs, could serve as individualizing characteristics. Finally, antemortem and postmortem data are compared to assess the likelihood of the match.

Due to fracturing, deformation, shrinkage, and color changes, the amount of osteological data that can be extracted and accurately assessed from burnt remains is often limited. A greater understanding of fire-related bone alteration can serve to extend this information and is critical for its interpretation. Commercial cremation is one of the more destructive treatments of human remains. This process involves burning the body until all organic materials are destroyed by heat, followed by pulverization of the burnt remains before returning the ashes to the family. Literature on human cremations published before the previous decade mostly focuses on archaeological remains. More recent publications pay more attention to forensic contexts, focusing on fire related macro- and microstructural changes to bone. Examination of human bodies in commercial cremations can provide an optimal assessment of the skeletal markers that are more resilient to fire destruction and thus more useful for determining the biological profile of burnt victims.

The material for study includes the analysis of 30 bodies submitted to commercial cremations from Memora Funeral Home (Salt, Girona, Spain). Standardized pre-cremation observations of the body were recorded before placing the body into the crematorium. After cremation, and before pulverization, standardized post-cremation observations of the remains were completed. The crematorium conditions (temperature and time of exposure) were essentially the same for all individuals included in the study. Pre-cremation data included sex, ancestry, age-at-death, body constitution, cause of death, dental data, and *postmortem* alteration during autopsy or embalming, as well as cremation parameters such as the presence of clothes or shroud, and body position in the crematorium. Post-cremation data collection included the surviving skeletal and dental elements that would allow assessment of sex, ancestry, age, pathology, and individual identification of the body and dental prosthesis recovered and their significance for identification, and bone and teeth alterations due to fire exposure.

The observed color spectrum went from the predominant white color expected from complete calcination to orange/brown tones observed in the spongy bone of vertebral bodies, the inner layer of cranial diploe, and the ribs. Gray colors could be observed in long bones. The colors observed in teeth were white and gray. Skeletal preservation was higher in male individuals, which could be attributed to the increased robusticity and body size of the male skeleton. Maxilla, mastoid processes, orbital ridges, vertebrae, coxae, and long bone epiphyses proved to be the most resilient areas, while ribs, cranial vault, and long bone diaphyses displayed the highest degree of deformation. Long bones generally showed the presence of curved transverse fractures and longitudinal fractures. Patina fractures were conspicuous on the surface of vertebral bodies. Cranial fractures often coincided with the suture lines, while mandibles often presented condyle fractures. This study showed that it was not possible to estimate stature in any case, due to heat alteration of long bones; however, the burned elements that contributed to sex assessment were sciatic notch, femoral and humeral heads, orbital ridge, mastoids,inion, and nuchal crest. Age assessment was more often possible from long bone epiphyses, teeth, and degenerative traits such as vertebral osteophytes or osteoarthritis in joints. Body and teeth prostheses and consolidated fractures provided individualizing characteristics.

Burnt Human Remains, Commercial Cremation, Skeletal Identification

Anthropology Section - 2015

A40 Does Aluminum Transfer to Bone When Used as a Packaging Medium? A Test Using X-Ray Fluorescence Spectrometry

Lyniece Lewis, BS*, George Mason University, 4400 University Drive, Fairfax, VA 22030; and Angi M. Christensen, PhD, FBI Laboratory, 2501 Investigation Parkway, Quantico, VA 22135

After attending this presentation, attendees will be familiar with the use of aluminum foil as a packaging medium for fragile skeletal material and understand whether this form of packaging affects the elemental properties of bone.

This presentation will impact the forensic science community by determining whether the use of foil to package skeletal material results in the transfer of aluminum to bone and by questioning whether foil should continue to be recommended as a packaging medium when subsequent elemental analyses may be performed on bones.

Skeletal evidence recovered in the field is typically placed into a packaging medium to preserve and transport the material to the morgue, laboratory, evidence storage, or other destination. Preferred packing methods involve considerations for preventing loss, cross-contamination, or deleterious change. Materials such as paper products (including paper bags, envelopes, and cardboard boxes) are often recommended for packaging skeletal material to offer protection and also to prevent mold growth, tissue breakdown, or other changes associated with confining the material with moisture.

Skeletal material that is burned or highly weathered is often considerably more fragile and at high risk for fragmentation during packaging and transportation. One method that has been suggested to stabilize and protect fragile skeletal material is to carefully wrap it in aluminum foil. This approach offers protection against further fragmentation and also maintains the relative anatomical positioning of bones and teeth at the time of recovery in the event that fragmentation does occur in transit. However, traces of aluminum are known to leach from foil and other aluminum packaging materials into food products and it is currently unknown whether transfer/leaching of aluminum or other elements to the bone may also occur. Chemical and elemental analyses are becoming more common in forensic anthropological examinations and transfer of aluminum or other elements to bones from packaging materials, if it occurs, could result in skewed elemental test results. This study used X-Ray Fluorescence (XRF) spectrometry to test whether the use of aluminum foil to package bones results in the transfer of aluminum from the foil to the bone.

Twenty-six deer bones were used in this study. Each bone was burned on one end using a hand-held butane torch, leaving the other end unaltered. Prior to placing the bones into aluminum packaging, each end of each bone was sampled twice using a hand-held XRF device to determine the baseline elemental profiles. A standard 120-second collection time was used and the data were saved as total photon counts in spread sheets. One specimen (used as a control) was packaged in brown paper with no foil and maintained at room temperature. The remaining 25 specimens, in sample groups of five, were then packaged in five different ways. Five specimens were packaged in new, flat foil and stored at room temperature. Since crumpling foil disrupts bonds and may increase the likelihood of aluminum transfer, five specimens were placed into foil that had been crumpled prior to use, and then stored at room temperature. Since elevated temperatures may also increase the likelihood of aluminum transfer, five specimens in flat foil and five specimens in crumpled foil were stored in the trunk of a car where temperatures reached up to 110°F. Finally, one group of bones was placed in foil, then exposed to excessive heat using a torch. Specimens were maintained in their packaging and stored for a period of six weeks.

After six weeks, each end of each bone was again tested using XRF. Paired t-tests of each of the five sample groups before and after six weeks in the aluminum packaging were used to determine whether the mean aluminum levels of the bone surface changed as a result of prolonged contact with aluminum foil. None of the differences in mean aluminum levels for any of the sample groups were significant ($p > 0.05$ for all groups). These results indicate that, even when physically compromised aluminum foil is used, and even when foil-packaged specimens are exposed to very high temperatures, significant aluminum transfer to the bone does not occur. Aluminum foil can therefore continue to be recommended and used as a packaging medium for bones without the risk of affecting subsequent elemental analyses.

Forensic Anthropology, Evidence Packaging, Elemental Analysis

A41 Fluorescence in Heat-Altered Bone Under Ultraviolet Light

Traci L. Van Deest, PhD*, Pima County OME, 2825 E District Street, Tucson, AZ 85714

After attending this presentation, attendees will be knowledgeable about the use of fluorescence under ultraviolet light in the examination of burned and heat-altered remains. Attendees will also learn what fluorescence can reveal about the bone properties and the parameters of the heat event.

This presentation will impact the forensic scientific community by exploring the use of fluorescence under ultraviolet light as a method for analysis of burned and cremated remains. The description of these types of cases has been largely qualitative; this research attempts to provide a low-cost, easily interpreted method of analysis of this type of anthropological casework.

Alternative light sources and fluorescence are methods that have a long tradition within the forensic sciences. Few studies have addressed fluorescence in burned and cremated human remains. Warren et al. mention it as part of the examination of commercially cremated remains and Harbeck et al. examine how fluorescence changes with differing temperatures of the heat event.^{1,2} In addition to understanding fluorescence changes with heat exposure, it is important to know what is underlying the fluorescence patterns to ensure reliability and applicability of the technique. Fluorescence results from an interaction of the excitation of light and the material under examination. The specific combination of excitation wavelength and fluorescence emission peak is indicative of the material under examination. Thus, fluorescence in burned bone can not only reflect the temperature of heat exposure, it also indicates what changes are taking place to bone properties.

The diaphysis of five pig femora were cleaned and segmented, with each exposed to a differing time and temperature combination. One segment was held at ambient temperature for a control; five segments were each subjected to temperatures between 100°C and 900°C in 200° increments for 60 minutes. To examine the impact of duration, a segment was heated at 500°C or 900°C for one of the following durations: 15, 30, or 45 minutes. Fluorescence data was collected using a spectrofluorimeter, as well as bone chemistry and composition analyses, to document changes to the skeletal tissue. Ultraviolet light between 300nm and 395nm at 5nm increments was used for excitation, with emission collected across the visible spectrum (400nm and 700nm).

Under excitation light similar to most Ultraviolet (UV) light sources (365nm), fluorescence changed based on temperature of exposure but not duration. The control samples and those heated to 100°C showed a bright blue fluorescence (~450nm peak). No fluorescence was seen in samples heated to 300°C and 500°C, with red fluorescence (>640nm) noted in samples heated to temperatures of 700°C and 900°C.

To investigate what excitation and emission combination resulted in fluorescence of the samples, an Emission Excitation Matrix (EEM) was collected for each bone segment. Parallel factor analysis of the EEMs for samples at all temperatures indicated two components best describe the dataset. The first component of the model (excitation=330nm, emission peak=696nm) is a red fluorescence. More research is needed to determine the underlying mechanism for this fluorescence. The second component (excitation=365nm, emission peak=458nm) characterizes blue fluorescence corresponding to the collagen and organic components in samples of low temperature exposure.^{3,4}

This research indicates that fluorescence under ultraviolet light can be used to assess not only the temperature of the heat event, but also indicate the bone properties. In order for fluorescence to be a reliable method, it is necessary to determine what changes in bone properties underlie the fluorescence after heat exposure. Based on this research, it is expected that bone exposed to low temperatures would exhibit blue fluorescence linked to collagen content; with complete or near-complete loss of fluorescence in the middle range temperatures, and a red fluorescence is expected at the higher temperatures.

A42 **Effects of Hydrated Lime and Quicklime on the Decay of Human Remains Using Pig Cadavers as Human Body Analogues: Field and Laboratory Experiments**

*Eline M.J. Schotsmans, PhD**, University of Bordeaux, UMR 5199 PACEA Bâtiment B8, Allée Geoffroy St Hilaire CS 50023, 33615 Pessac Cedex, Aquitaine, FRANCE

After attending this presentation, attendees will understand the short- and long-term effects of hydrated lime and quicklime on the decomposition of human remains. An increased number of police inquiries involving human remains buried with lime has demonstrated the need for more research into the effect of different types of lime on cadaver decomposition and its micro-environment.

This presentation will impact the forensic science community by showing results that have implications for the investigation of time-since-death of limed remains and potentially for the interpretation of clandestine burials, mass graves, and management of mass disasters by humanitarian organizations and Disaster Victim Identification (DVI) teams. Knowledge of the effects of lime on decomposition processes is of interest to forensic pathologists, archaeologists, humanitarian organizations, and those concerned with disposal of animal carcasses or human remains in mass disasters.

Contradictions and misconceptions regarding the effect of lime on the decay of human remains have demonstrated the need for more research into the effect of different types of lime on cadaver decomposition.

In this study, a series of field and laboratory microcosm experiments are presented studying the effects of lime. Six pig carcasses (*Sus scrofa*), used as human body analogues, were buried without lime, with hydrated lime (Ca(OH)_2), and with quicklime (CaO) in shallow graves in sandy-loam soil in Belgium and recovered after 6, 17, and 42 months of burial. Analysis of the soil, lime, and carcasses included entomology, pH, moisture content, microbial activity, histology, and lime carbonation. The results of this study demonstrate that despite conflicting evidence in the literature, the extent of decomposition is slowed down by burial with both hydrated lime and quicklime. The more advanced the decay process, the more similar the degree of liquefaction between the limed and unlimed remains. The end result for each mode of burial will ultimately result in skeletonization. A further three pig carcasses (*Sus scrofa*) were observed and monitored for 78 days without lime, with hydrated lime, and with quicklime in a taphonomy laboratory. The results showed that in the early stages of decay, the unlimed and hydrated lime cadavers follow a similar pattern of changes. In contrast, the application of quicklime instigated an initial acceleration of decay. Microbial investigation demonstrated that the presence of lime does not eliminate all aerobic bacteria. The experiment also suggested that lime functions as a sink, buffering the carbon dioxide evolution. In the absence of other studies on lime in graves, this research produces valuable and novel information of interest to the forensic society.

Lime, Taphonomy, Differential Decomposition

A43 Assessing How Repetitive Carrion Placement Affects Vulture Scavenging Behavior

*Lauren R. Pharr, MA**, Louisiana State University, Dept of Geography & Anthropology, 227 Howe-Russell Geoscience Complex, Baton Rouge, LA 70803; *Michael Leitner, PhD*, Louisiana State University, Dept of Geography and Anthropology, 227 Howe-Russell Geo Complex, Baton Rouge, LA 70803; and *Mary H. Manhein, MA*, Louisiana State University, Dept of Geography & Anthropology, Baton Rouge, LA 70803

After attending this presentation, attendees will be aware of how sites with repetitive carrion placement, such as an outdoor forensic facility, affect animal scavenging rates and behavior. Attendees will also become aware of the applicability of temporal scavenging data collected at the Texas State Forensic Anthropology Research Facility (FARF) to forensic contexts that lack the continuous carrion presence found at this FARF.

This presentation will impact the forensic science community by addressing the possibility of learned behavior and accelerated arrival times in avian scavengers at the FARF as a result of repetitive decomposition studies occurring at this site.

In recent years, forensic anthropology research facilities have gained much attention because they offer a means of conducting decomposition research that seeks to benefit law enforcement. These outdoor decomposition facilities provide invaluable skeletal data with associated demographics, but no researchers have investigated the impact these facilities may be having on vertebrate scavenging behavior. This study focuses on vulture scavenging behavior and addresses the possible variability in vulture scavenging rates at the FARF as a consequence of repetitive decomposition studies occurring at this site.

To address the possibility of learned behavior in vultures scavenging at the FARF, a series of 14 decomposition trials were conducted at three site types over a two-year period to test the hypothesis that the type of scavenging site affects the amount of time between carrion exposure and the initiation of a vulture scavenging event. Each trial involved placing a single juvenile pig at each of the three site types, which included the following: (1) Texas State FARF — repetitive carrion placement in a single location; (2) Rotate Sites — repetitive carrion placement at different locations; and, (3) Stationary Site — repetitive carrion placement in a single location. The FARF and Stationary Sites were over 1km apart and the Rotate Sites were distributed across an area of 6,000km² spanning from Austin to San Antonio. The three pigs used in each trial were placed in uncaged locations on a single day. All sites were equipped with a motion-activated infrared wildlife camera and a weather station programmed to record climatic variables using one-minute sampling intervals. The cameras and the weather stations were in operation 24 hours a day throughout the duration of the study.

Temporal data were calculated for minutes between researcher departure from the site until the time of vulture arrival at the carrion. Departure time was chosen based on the assumption that vultures would not arrive while a human was at the site. In addition, Accumulated Degree Minutes (ADM) were calculated for the time between pig placement and vulture arrival to account for the assumption that vulture arrival at carrion is based on their detection of temperature-dependent volatiles being omitted during different stages of decomposition. To account for some of the pigs being placed in the evening after vultures had returned to their roosts, a second ADM value was calculated for temperatures only recorded during the day. Solar radiation values of 0.6 W/m² (i.e., nighttime) were used to distinguish daytime and nighttime temperature values.

One-way Analysis of Variances (ANOVAs) testing for differences between the type of scavenging site and time of vulture arrival were performed on the three temporal values described above and reveal an absence of statistical differences between site type and vulture arrival times. Results also indicate that scavenging rates obtained through the FARF research are applicable to scavenging rates occurring outside of FARF within the 6,000km² geographical range used in this study so long as the carrion size, type, and stage of decomposition are the same between the FARF and the location in question. Furthermore, the similarity between scavenging rates at the FARF and other sites were based on carrion placement occurring two weeks apart, which suggests this may be a best practices temporal benchmark for future scavenging studies. Lastly, this study reveals that although variation exists in vulture scavenging rates, the repetition of carrion using two-week intervals at a particular site does not accelerate or cause differences in vultures' arrival time at recently exposed carrion.

Vulture Scavenging, Carrion, Taphonomy

Anthropology Section - 2015

A44 **Burning Models: Human vs. Pig in Taphonomic Fatal Fire Modeling**

*Elayne J. Pope, PhD**, Tidewater OCME, 830 Southampton Avenue, Ste 100, Norfolk, VA 23510; and *Mike Whitney*, San Luis Obispo Fire Investigation Strike Team, PO Box 1041, Atascadero, CA 93423

The goal of this presentation is to understand the fundamental differences between how the human body burns and how a pig burns which are two different processes and have two distinct outcomes. Results from 12 bodies (n=6 pigs and 6 humans) that were burned under similarly replicated conditions with direct and radiant heat produced early-to-advanced heat-related changes to the respective human or pig body. Pig tissues differ from human tissues in their thickness, configuration, and organization.

This presentation will impact the forensic science community by answering the question, “Is it reasonable to model burn patterns on tissues that are not of human origin, such as the pig, in fatal fire modeling?” This research will demonstrate that no, the pig is not an acceptable model to use in fatal fire modeling for a number of reasons that include their comparative soft tissues of skin, muscle, and fat, and the differences of the musculoskeletal systems.

Forensic taphonomic modeling has been peppered with the use of porcine models, since they are said to be, “the most similar to the size, shape, and anatomy of the human torso.” In fact, the pig model has become the standard species used to replicate a wide variety of decompositional studies, along with other similar-sized animals such as deer or sheep. Anatomy of the thoracic cavity and abdomen of pigs may be similar to humans, but when it comes to areas of the head and the limbs; the parallels cease to exist. Likewise, the soft tissues themselves respond differently in the porcine model than what occurs in the human tissues of the skin, the underlying subcutaneous fat, muscles, tendons, and, ultimately, the bones. To fairly test the differences between the two species, a total of six young (100+lb) pigs and six adult unembalmed human bodies were burned together within the same fire environments on three separate occasions to discern similarities and differences of the burn patterns and to answer the question, “Is it a good idea to use pigs/quadrupeds for fire modeling in taphonomic research when drawing human comparisons in fatal fire modeling of forensic casework?”

Pig skin is much thicker than human skin. Human skin is thin and elastic and is the first boundary to heat exposure; it therefore exhibits the earliest heat-related changes of the body. Human skin splits several minutes into the fire, while the thicker pig skin takes longer to split (>ten minutes). The biggest difference between the two is the fact that humans have a healthy layer of subcutaneous fat underneath the skin, whereas young pigs are solid muscle under their skin and lack this important layer of soft tissue. This difference is the one of the major flaws with using pigs to model humans in fatal fire modeling. The human body’s thin elastic skin and abundant underlying subcutaneous fat plays a huge role in the burn patterns that are unique to the human body as well as the burning process as time passes during the fire. Another major difference in this study was that the pig bone was young and had immature developing bone with the epiphyses and young joint structures. When the smaller limbs of pigs flexed, the entire joint surface became exposed along with the epiphyses and diaphyses of the pig knuckles. Flexion of the limbs was a major difference between pigs and humans as short quadrupedal anatomy cannot replicate the lengthier human form, particularly of the upper body. Likewise, the musculoskeletal anatomy of the human and pig head does not warrant comparison due to differential buttressing of the pig’s face and skull that differs from that of the human’s unique craniofacial complex. These are several reasons to discourage the use of pigs as human models when it comes to fatal fire modeling where literal comparisons may be based off of the burn patterns.

Fatal Fire Modeling, Burn Patterns, Pig or Human

Anthropology Section - 2015

A45 A Multidisciplinary Validation Study of Non-Human Animal Models for Forensic Decomposition Research: A Time Series Approach

Angela M. Dautartas, MA*, 250 S Stadium Hall, Knoxville, TN 37996; Lee Meadows Jantz, PhD, University of Tennessee, Dept of Anthropology, 250 S Stadium Hall, Knoxville, TN 37996-0720; Giovanna M. Vidoli, PhD, University of Tennessee, Dept of Anthropology, Knoxville, TN 37917; and Dawnie W. Steadman, PhD, University of Tennessee, Dept of Anthropology, 250 S Stadium Hall, Knoxville, TN 37996

After attending this presentation, attendees will better evaluate the validity of pig and rabbit proxies for human decomposition studies, particularly for time-since-death estimation. Attendees will also understand the applicability of time series analysis to decomposition studies.

This presentation will impact the forensic science community by demonstrating whether non-human animal data could be admissible in court when applied to human remains in forensic contexts.

Animal proxies are often utilized in decomposition studies in cases where human remains are unavailable. The most frequent animal subjects found in the literature are pigs, although rabbits, guinea pigs, dogs, and other models have been studied; however, the scientific merit of non-human models for forensic applications, including estimation of the postmortem interval, has never been formally tested.

The goal of this project is to directly compare decomposition data among three species — pigs, humans, and rabbits — in three separate trials that differ by microenvironment and season. Variables which have been documented include insect activity (fly oviposition, the developmental stage of immature insects, fly larval migration, emergence of adult arthropods, and succession), morphological changes of the body, scavenging, and climatic conditions. The results of the first trial are presented here and focus on the comparison of morphological changes over time.

On March 13, 2014, five pigs, five humans, and five rabbits were placed in a previously unused, wooded area of the Anthropological Research Facility at the University of Tennessee, Knoxville. After initial placement, the subjects were photographed twice daily and external signs of decomposition were recorded for 75 days. Total body scores as well as scavenging and insect data were determined for each subject at each observation period.¹ Temperature readings were collected from three data loggers placed approximately 1.5 meters above ground throughout the research area; body core and adjacent soil temperatures were collected as well. Data continued to be collected twice daily until 2,000 Accumulated Degree Hours (ADH) had been reached; data collection then continued once daily, then decreased to every other day until the end of the sampling period on May 27, 2014.

Insect activity and external signs of decomposition during the first trial suggest that the pattern of decay is not identical across species. The rabbits exhibited few external signs of decomposition, then appeared to decompose very rapidly with the onset of larval activity. The pigs and humans were more similar to each other in their rates of decomposition. Both species showed external signs of early decomposition, including color changes and skin slippage. Patterns of insect activity were also more similar between pigs and humans, with multiple distinct maggot masses observed on each subject, as opposed to a single mass observed on each of the rabbits. Humans exhibited greater variability with respect to both visual decomposition changes and insect activity than either pigs or rabbits. In addition, only the human subjects had any evidence of scavenging; this further distinguishes them from the pig and rabbit subjects.

Time series statistics were used to evaluate these observations with an objective, quantitative approach. In the analyses, the average daily temperature data were compared to the average daily total body scores for each species. Dynamic linear regression was chosen to build a model of how total body score changed over time, with the corresponding change in temperature incorporated as an impacting factor. Mean square error was used as a search criterion as this statistic informs whether or not the model is a good fit to the data. Preliminary results of this analysis of each species showed that the temperature data correlated more closely with the total body scores of the humans and pigs than with the rabbits (mean square error 3.68, 3.89, and 6.83, respectively). As with the visual observations, this suggests that the pattern of decomposition differs between the species and, as such, the three groups are not likely to be interchangeable in decomposition research.

A46 Identification of Osteological Remains From the Ironclad U.S.S. *Monitor*

David R. Hunt, PhD*, Smithsonian Institution, Dept of Anthropology/MRC112, 10th and Constitution Avenue/NMNH, Washington, DC 20013-7012; David Krop, MA, Mariners' Museum, 100 Museum Drive, Newport News, VA 23606; Kathleen Sullivan, MAC, Mariners' Museum, 100 Museum Drive, Newport News, VA 23606; Jeremy Jacobs, MS, Smithsonian Institution, National Museum of Natural History/VZ, 10th and Constitution Avenue, Washington, DC 20013; John Ososky, MS, Smithsonian Institution, National Museum of Natural History/VZ, 10th and Constitution Avenue, Washington, DC 20013; and Charley Potter, BS, Smithsonian Institution, National Museum of Natural History/VZ, 10th and Constitution Avenue, Washington, DC 20013

The goal of this presentation is to expose attendees to the possible misidentification of human remains as marine mammal remains.

This presentation will impact the forensic science community by cautioning against misidentification of human remains as turtle remains.

In 2001, National Oceanic and Atmospheric Administration (NOAA) archaeologists and United States Navy salvage divers recovered the main steam engine from the Civil War ironclad U.S.S. *Monitor* which sank off the coast of North Carolina in 1862. The engine was then transferred to The Mariners' Museum (TMM) in Newport News, VA, for documentation, conservation, and exhibition. Additional artifacts like the ship's 120-ton revolving gun turret and personal items were recovered in 2002. The archaeological collection now totals nearly 1,500 artifacts. While surveying this collection, museum conservators discovered an unprovenienced bone. The size and morphology of the bone was quite similar to a human phalanx, having what appeared to be a dual-faceted proximal articulation with tapering diaphysis from the preserved articular end to a widening distal articular end that was broken at the neck of the distal diaphysis. Sixteen sailors perished during the sinking of the U.S.S. *Monitor* and there was some concern that this bone was remains from a lost sailor; however, TMM conservators also discovered the incomplete remains of a sea turtle concreted to the ship's main engine. Portions of the head, carapace, and appendages were documented and removed for conservation. As a result, TMM conservators questioned whether the particular unprovenienced bone was human or non-human in origin.

The possible phalanx, as well as the recovered turtle bones, was brought to the Smithsonian Institution for examination. Human hand and foot elements from the anatomical series were compared to the bone. The morphological structure was more similar to a medial hand phalanx than to a foot phalanx, but there were no clear indications of lateral ridges for the flexor tendon insertion and the cross section of the diaphysis was more oval in shape than the more typical "D" shape of the human proximal and medial phalanges.

For sea turtles, there are six species possibilities along the Atlantic Ocean coast. From examination of the turtle bones from the U.S.S. *Monitor*, the lower jaw and humeri were most diagnostic for the loggerhead turtle (*Caretta caretta*). Using the mandible from the turtle remains for size comparison, digit bones from similar-sized specimens in the Amphibian and Reptile Osteological collections were reviewed and it was established that the bone is extremely similar to the medial phalanx from the front flipper of a loggerhead turtle. Thus, the bone in question is considered to be from a loggerhead turtle and likely the same turtle found in the engine room. DNA analysis would be necessary to confirm association.

Although a situation such as this investigation would be exceedingly rare in "normal" forensic settings, the results of this comparative examination show that there are elements of turtle species that are highly similar in morphology to human elements. In coastal regions where marine turtle species skeletons may be found, it should be noted that these remains may be misinterpreted as human.

Bone Identification, Skeletal Morphology, Human vs. Non-Human

A47 **The Afghan Forensic Science Organization: A Model for Local Capacity Building for Mass Grave Documentation and Preservation in Afghanistan**

*Zabi Mazoori**, Physicians for Human Rights, 256 W 38th Street, New York, NY 10018; *Gillian M. Fowler, MSc**, University of Lincoln, School of Life Sciences, Brayford Pool, Lincoln LN6 7TS, UNITED KINGDOM; *Dallas Mazoori, JD**, Physicians for Human Rights, 256 W 38th Street, 9th Fl, New York, NY 10018; and *Stefan Schmitt, MS**, 313 Garner Court, Tallahassee, FL 32301

After attending this presentation, attendees will be aware of the goals and objectives of the Afghan Forensic Science Organization (AFSO) and their work in Afghanistan, a country in which more than 30 years of armed conflict has produced countless victims who are listed as missing. Since the United States intervention in October 2001, which liberated the country from Taliban rule, there has not been an effective transitional justice effort tied to the country's developing judicial system.

This presentation will impact the forensic science community by highlighting the importance of long-term dedication to building local capacity in forensic investigations and the role an independent non-governmental organization can play in such settings. The difficulties encountered in this project and the steps taken in an attempt to overcome them will also be presented.

Since 1997, Physicians for Human Rights (PHR) has dedicated itself to creating, supporting, and enhancing a transitional justice strategy in Afghanistan, a society that has suffered decades of continual armed conflict as well as innumerable tragedies inextricably intertwined with conflicts of such duration and intensity. PHR conducted its first forensic work in Afghanistan in 1997 under the auspices of the United Nations Office of the High Commissioner for Human Rights, documenting a mass grave found on the outskirts of Sheberghan in the northern part of the country. Since then, PHR has forensically documented numerous mass grave sites in Afghanistan.

In October 2009, with the support of the United States Department of State's Bureau of Democracy, Human Rights, and Labor, PHR initiated a three-and-a-half-year project, "Securing Afghanistan's Past." The AFSO, a new independent organization, was founded as an outcome of the training carried out under this grant. This organization was formed in 2011 by members of the Afghan National Police (ANP), the Afghan National Police Academy (ANPA), the Legal Medicine Department (LMD), the Afghan Independent Human Rights Commission (AIHRC), and various civil society organizations as a result of a 2010 six-week training course by PHR covering evidence and crime scene documentation and forensic anthropology.

Throughout Afghanistan's decades of conflict, Afghan scientists and scholars have been isolated from modern education and the academic world. International donors and the government of Afghanistan should, therefore, identify and prioritize funding for the increased development of Afghanistan's higher education system, particularly for those who must necessarily play a role in its forensic future, such as judges, prosecutors, attorneys, scientists, and medical professionals.

The AFSO provides a non-governmental, independent organization which can assist in the development of a national forensic capacity. Despite the immense scale of the disappeared-persons issue in Afghanistan, there has been little to no official acknowledgment of disappearances that have occurred throughout the conflict, nor any real effort to find the missing and disappeared or to hold alleged perpetrators accountable. The right of families to know the truth surrounding the fate of a missing family member is an essential part of any developing judicial system. AFSO and its work represent the first small steps on the path to reconciliation and transitional justice.

Mass Graves, Afghanistan, Physicians for Human Rights

A48 Skeletal Markers of Gender Reassignment

Michael W. Warren, PhD, C.A. Pound Human ID Laboratory, Cancer & Genetics Research Complex, 2033 Mowry Road, Rm G-17, Gainesville, FL 32610; Caley Roberts, BA, University of Florida, Turlington Hall, Rm 1112, PO Box 117305, Gainesville, FL 32605; and Kristina B. Altes, MA, 3224 NW 31st Avenue, Gainesville, FL 32605*

After attending this presentation, attendees will recognize potential skeletal indicators of male-to-female gender transition and will be aware of some traits that should be regarded with caution when transgenderism is suspected.

This presentation will impact the forensic science community by providing a case study for sex assessment in male-to-female transgender individuals.

In 1988, a decomposing human body was found in a wooded area of central Florida. The remains were found in association with several articles of female clothing, including a denim skirt, blouse, and pantyhose. Two silicone breast implants were also found in close association with the remains. A limited autopsy was performed in which it was noted that the pelvis was of “female type.” The body was decomposed to the extent that external genitalia were not present and the absence of a uterus was attributed to a probable hysterectomy. The case was referred to an anthropologist, who noted the presence of preauricular sulci and dorsal pitting which was interpreted as evidence of childbirth. The anthropologist’s report listed the decedent as female. During a review of cold cases for submission of DNA samples, the case was re-evaluated. The skeletal morphology strongly suggested that the decedent was a male. The female clothing, breast implants, cosmetic rhinoplasty, and pits of parturition were interpreted as evidence for gender reassignment surgery and normal sequelae associated with estrogen supplementation and/or androgen suppression treatment. A new anthropology report listing the sex of the decedent as male was submitted with bone samples to the University of North Texas Center for Human Identification, who were able to sequence mitochondrial DNA for the decedent. The DNA sample confirmed that the decedent was born a male.

The medical literature addresses possible skeletal effects related to the medical and surgical treatment of gender dysphoria, primarily related to bone density; however, little is known about the expression of those effects in dry bone. This case presents preliminary information about skeletal changes and contextual evidence that may alert an anthropologist that the decedent is male-to-female transgendered, aiding greatly in the investigation of the death. This case also demonstrates how new scientific findings can change interpretations over time. In this case, after the initial anthropological analysis, research was published related to the production of the hormone relaxin in males; this research was helpful in conducting the second examination of the remains. This case exemplifies the need for the field to evolve in accordance with changing demographic trends, as well as with new research that may not be entirely confined to biological anthropology.

A49 Ritualistic Use of Human Skeletal Remains: Is It Forensically Significant?

Ashley Green*, 13858 Valleybrooke Lane, Orlando, FL 32826; John J. Schultz, PhD, University of Central Florida, Dept of Anthropology, 4000 Central Florida Boulevard, HPH 309, Orlando, FL 32816; and Jan C. Garavaglia, MD, District 9 ME, 2350 E Michigan Avenue, Orlando, FL 32806

After attending this presentation, attendees will have an increased understanding regarding the recognition of human skeletal remains and associated artifacts used within the rituals of Palo Mayombe, as well as of the determination of the forensic significance of these skeletal remains. This presentation will focus on at least six Palo Mayombe case studies in which human remains were recovered within the central Florida area in order to discuss criteria for recognizing these types of ritual remains.

This presentation will impact the forensic science community by discussing the criteria used to recognize Palo Mayombe scenes with human skeletal remains. In addition, an overview of the common methods of procurement of human skeletal remains used by the practitioners for these rituals will be discussed.

Palo Mayombe, an Afro-Caribbean syncretic religion originating from the Bantu regions of the African Congo, is of particular interest to the forensic community as one of the main components of the religion is the use of human skeletal remains in ritual. Practitioners use human skeletal remains in order to communicate with the deceased and to harness the power of the dead to influence undertakings in the lives of the practitioners.^{1,2} The power of the deceased may be used for either benevolent or malevolent purposes, depending upon the will of the practitioner.^{1,3} Human skeletal remains are most commonly found contained within and in the immediate vicinity of the *nganga*, an iron cauldron containing specific objects chosen according to the spirit with whom they are associated, such as animal carcasses, graveyard soil, herbs, mercury, assorted metal objects, colored beads, feathers, blood, sticks (*palos*), and stones (*otanes*).^{1,3} The most common human skeletal elements found within the *nganga* include the skull, tibia, femur, ribs, and phalanges.³ Of particular significance is the presence of a tibia wrapped in black cloth, which is used as a scepter, or an animal horn, both of which are used by the priest (*palero*) to summon the spirits.¹ This aspect of ritual is especially important, as the forensic anthropologist will often be involved in determining forensic significance of the human skeletal remains discovered within this context.

The sacred space in which the *nganga* resides is often key in the identification of Palo ritual. Examples of these spaces will be detailed in the case studies presented. The space will contain elements of nature such as greenery, animal heads and skins, wooden branches, or stones, and will also be painted in the religious language of Palo, the *firma*, which are religious symbols, drawn within the space to signify intent to make contact with the spiritual realm.⁴ Oftentimes, there will also be pieces of metal, figurines, crosses, and other artifacts symbolic of the nature spirit (*Mpungo*) with whom the *palero* associates.^{1,3}

This presentation will focus on at least six Palo Mayombe cases that were discovered in central Florida. Crania, skulls, and post-cranial skeletal material were discovered within *ngangas*, yielding information useful to the forensic community in properly identifying archaeological and anatomical teaching specimens when discovered in this unique context. The cases from central Florida comprise different settings in which human skeletal remains were discovered and include a shed in the practitioner's backyard, a warehouse, and the disposal of a *nganga*, presumably upon the death of a *palero*, on the bank of a river. The most common sources of procurement for skeletal material used for Palo Mayombe include grave robbing, botanicas, and the legal purchase of anatomical specimens from anatomical supply companies through the internet. Associated artifacts and the presence of religious symbols will also aid in recognition of religious ritual. In two of the cases, forensic significance of the human skeletal remains was confirmed with documentation of the purchases that was provided by the practitioners (receipts and tags).

Forensic, Palo Mayombe, Ritual

A50 Regression Analysis for Estimation of Stature From Foot Lengths in a North Indian Population

Kewal Krishan, PhD, Panjab University, Dept of Anthropology, Sector 14, Chandigarh 160 014, INDIA; and Tanuj Kanchan, MD, Dept of Forensic Medicine, Light House Hill Road, Mangalore, Karnataka 575 001, INDIA*

After attending this presentation, attendees will understand the usefulness and methodology of stature estimation, especially from various length measurements of the foot, which will be helpful in conducting further research in this area and in studying forensic cases usually encountered in airplane crashes, intentional mutilation and dismemberment, explosions, or other mass disasters.

This presentation will impact the forensic science community by presenting standards for stature estimation from various length measurements of the feet when feet or parts thereof are presented for forensic examination.

Establishing identity is one of the primary goals of any medicolegal investigation, especially when human remains are brought in for examination. These remains may be in the form of dismembered and mutilated body parts or skeletal remains. The identification process involves the estimation of a biological profile of the decedent which includes estimation of age, sex, stature, and race or ethnicity. A biological profile derived in this manner is a circumstantial identification that narrows the comparative pool of potentially matching profiles and thus helps in medicolegal investigations. Estimation of stature is an essential parameter of identification that helps in establishing personal identity of the deceased. This complements other details on the age, ethnicity, and sex in the identification of skeletal remains and body parts. In this context, the present study was conducted in order to make regression models for estimation of stature from five specific foot lengths in a north Indian population. This study is based on a random sample of 700 adults (500 males, 200 females) ranging in age from 18 to 30 years old. In addition to stature, five separate foot length measurements were taken from each subject (length of the foot from each toe; i.e., T1, T2, T3, T4, and T5, respectively) according to standard procedures and landmarks. The data were statistically analyzed using Statistical Package for Social Sciences (SPSS), version 11.0, computer software. Sex differences in stature and foot measurements were analyzed using Student's t-test. Karl Pearson's correlation coefficients were calculated between stature and various length measurements of the foot. The stature was estimated from various length measurements of the foot using both linear and multiple regression analyses.

Mean stature of the sample was 170.3cm and 157.9cm in males and females, respectively. Length measurement at the first toe (T1) was found to be the longest in both the sexes on the right and left sides. Statistically significant sex differences were observed in the length measurements on the foot between males and females in right and left feet ($p < 0.001$). Statistically significant correlation coefficients ($p \leq 0.001$) were observed for correlation between stature and various foot length measurements in males, females, and the pooled sample. Thus, the stature was found to be positively and strongly correlated to various foot length measurements in both the sexes. In males, the correlation value (r) ranged between 0.628 and 0.641, while the range in females was between 0.539 and 0.657; however, the correlation coefficient in the pooled sample ranged between 0.746 and 0.776. Thus, the pooled sample showed relatively higher values of correlation coefficients than in males and females separately. The linear and multiple regression models were derived for estimation of stature from foot length measurements in males, females, and the pooled group. While estimating stature from linear regression models of all the right and left foot length measurements, the Standard Error of Estimate (SEE) in the case of females (3.5cm) was lower than that of males (5.3cm), indicating that female feet give a better estimate of stature than male feet. The pooled sample showed a similar SEE as that observed in males. Multiple regression models showed a marginally better, but similar, trend of accuracy as that shown in the males, females, and the pooled group in the linear regression analysis.

The study was conducted as a part of a major research project funded by University Grants Commission, New Delhi, vide grant no. F.No. 34-120/2008 (SR), dated January 2, 2009.

Personal Identification, Stature Estimation, Foot Length Measurements

Anthropology Section - 2015

A51 Sexual Dimorphism of the Zygomatic Bone in a Southeast Asian Sample

Rebecca J. Wilson-Taylor, PhD*, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853

The goal of this presentation is to inform attendees of the potential use of the zygomatic bone in assessing sex during the construction of a biological profile.

This presentation will impact the forensic science community by providing the foundation for developing a discriminant function equation using three linear measurements from the zygomatic bone to estimate the sex of fragmentary human remains.

The attribution of sex is an important component of the biological profile, but is often complicated by the lack of the most diagnostic elements typically used for sex estimation in fragmentary human remains. Prior research has suggested the zygomatic bone, a bone that is often recovered in the archaeological context, is sexually dimorphic. The Workshop of European Anthropologists noted an increased robusticity of the marginal process in European males, where Woo noted a maximum height and width difference between males and females in an English anatomical collection, and Wilson noted a size and shape difference between modern American White males and females from the William M. Bass Collection.¹⁻³ Specifically, Wilson demonstrated, through the use of geometric morphometrics, that the shape of the zygomatic bone can discriminate between American males and females at an 86% classification rate; however, digitizing a single element is not always practical or available to forensic practitioners, necessitating methods that use traditional caliper-based measurements.³ Further, prior research only evaluated samples from European populations. Thus, this research utilized a Southeast Asian sample to determine the discriminatory power of three linear measurements of the zygomatic bone for sex estimation.

The maximum height and width of the zygomatic bone, defined previously, and the maximum width of the frontal process, defined for this study, were collected from the left and right zygomatic bones of 202 modern Southeast Asian individuals (102 females aged 26-84 years and 100 males aged 22 to 96 years) housed at Khon Kaen University (KKU), Khon Kaen, Thailand, using sliding calipers.² Measurements were obtained from individuals for whom complete, unfractured zygomatic bones were available. Independent t-tests determined that no significant difference ($p\text{-value} > 0.05$) existed between the left and right sides for all three measurements; therefore, all subsequent analyses used pooled samples. All analyses, including a linear discriminant function analysis, were conducted using a statistical computing software.

The mean maximum height of the zygomatic bone is 48.2mm (95% SD=3.4mm) in males and 45.4mm (95% SD=3.3mm) in females, the mean maximum width of the zygomatic bone is 54.7mm (95% SD=3.7mm) in males and 50.8mm (95% SD=3.8mm) in females, and the mean maximum width of the frontal process of the zygomatic bone is 14.7mm (95% SD=2.2mm) in males and 12.6mm (95% SD=1.8mm) in females. A linear discriminant function analysis demonstrated that all three measurements are important in discriminating between Thai males and females, with the maximum width of the frontal process contributing more than the other two measurements. Further, the combination of these three measurements correctly classified 75% of the sample (74.5% of males and 75% of females).

When compared to previous research, the maximum height and width of the Thai zygomatic bone is larger than the modern American zygomatic bone for both males and females. This is not unexpected, as several researchers have noted population differences in the zygomatic bone, with individuals of Asian ancestry having larger malar regions. Future validation testing will need to test the universality of any discriminant function equations from the linear measurements due to this size difference. Additionally, the size differences between males and females in the Thai sample are less than those in the American sample, which supports the belief that Southeast Asians are less sexually dimorphic than Americans. Nevertheless, differences in the linear measurements from both samples are significant and can discriminate between males and females, which lends credence to the utility of the zygomatic bone as a criterion for assessing sex in fragmentary remains.

A52 Age Estimation in Modern Individuals Between Birth and Fourteen Years of Age Using Measurements of the Knee Joint

Melanie E. Boeyer, BS*, 5044 E Oak Ridge Circle, Erie, PA 16509; and Stephen D. Ousley, PhD, Dept of Applied Forensic Sciences, Dept of Anthropology, 501 E 38th Street, Erie, PA 16546

After attending this presentation, attendees will understand the growth and development of the knee joint and how it can aid in age estimation, as well as becoming familiar with the radiographic data bank, PATRICIA, and how it can be used in further growth and development research.

This presentation will impact the forensic science community by providing an alternative to other age-estimation methods. Additionally, this presentation will illustrate the importance of large-scale databases and their contribution in estimating the normal growth curve and in detecting secular changes.

Age estimation of the juvenile skeleton has primarily been dominated by dentition, as it is less likely to be subjected to environmental factors; however, in many circumstances, the dentition is not recovered, forcing anthropologists to use other areas of the skeleton for age estimates.¹ The ossification patterns and fusion timing of the knee joint can provide a wealth of information in regard to age, especially for individuals between birth and two years of age. Despite the abundance of information available from this region of the skeleton, especially through radiographic analysis, very little research has been published in regard to metric assessment. The purpose of this study is to provide a method of juvenile age estimation using metric analyses of radiographic images.

Nine measurements were taken on a sample of more than 1,000 radiographic images of modern children between the ages of birth and 14 years. Six ratios have a statistically significant relationship with age and were analyzed using linear regression. For example, tibial metaphyseal breadth and tibial epiphyseal breadth show two distinct linear trends, forming a clear “elbow” prior to data transformation, suggesting a well-defined lower bound just after birth that can be used to estimate post-birth age versus fetal age; however, most of the data required transformation to better model the relationship between chronological age and measurement ratios from the knee. Each of the six ratios were squared and cubed to be analyzed using linear regression. Moreover, all statistically significant linear regression models exhibit adjusted R² values that were 0.90 or greater, suggesting a strong relationship between chronological age and measurement ratios from the knee. All statistically significant linear regression models were also evaluated using 95% prediction intervals; however, due to the nature of the growth curves and the forensic questions being asked, the derived lower bounds appear to be more useful.

The data also suggest that the growth and shape changes of the proximal fibula are significantly less important than those changes seen in the distal femur and proximal tibia; however, appearance of the proximal fibular head epiphysis proved to be useful and was seen in individuals as young as 1.87 years of age.

In metrically evaluating knee development, outliers were detected which included individuals with Osteochondrosis (OCD) and Cornelia de Lange Syndrome, both of which delay skeletal development. These individuals were noted as lying significantly below the normal growth curve, suggesting that this type of data may also be useful in detecting child abuse in living individuals.

Other statistical methods, including Multivariate Adaptive Regression Splines (MARS) and Partial Least Squares provide estimates that better adjust for the multicollinear nature of the measurements. These techniques will more accurately model the post-birth growth spurts, while simultaneously accounting for the deceleration in growth following puberty.

This study illustrates the importance of not only large-scale, modern, reference data banks, but also of metric observations and modern statistical methods for estimating age of the juvenile skeleton.

Growth and Development, Radiographic Data Bank, Knee Joint

A53 Femoral Midshaft Shape: An Indicator of Adult Age-at-Death?

Megan E. Ingvaldstad, PhD*, JPAC Central ID Laboratory, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853; and Pierre M.M. Guyomarc'h, PhD, University of Bordeaux, UMR 5199 PACEA - A3P, Bordeaux 33000, FRANCE

After attending this presentation, attendees will understand that the cross-sectional shape of the adult human femoral midshaft is highly variable and that discovery of a uniform shape transformation pattern among this variability may allow for production of age-at-death ranges from unidentified skeletal remains.

This presentation will impact the forensic science community by eliminating a method proposed to utilize femoral midshaft cross-sectional shape to produce age-at-death estimates from unidentified adult human skeletal remains.

Literature review indicates anterior-posterior elongated femoral cross-sections are associated with great workload and mobility. This finding has been utilized previously to reconstruct behavioral differences, such as sexual division of labor and subsistence strategy within and between past populations; however, recent transversal biomechanical data reveals the femoral midshaft changes in size and shape throughout adulthood: once the human femur is fully developed, biomechanically adapted, and periosteally adjusted by adjacent musculature a net loss of cortical area begins as the amount of bone deposited on the periosteal surface lessens in comparison to the amount of bone removed from the endosteal surface. Additionally, analysis of shape ratios and the angle formed between the I_{\max} biomechanical axis and the medial-lateral anatomical axis indicates young adults often have anterior-posterior elongated cortices but mature adults increasingly display circular to medial-lateral elongated cortices.

Because members of modern industrialized society are not expected to display evidence of a sexual division of labor or differential subsistence strategies, this study hypothesized that femoral cross-sectional shape variability could partially reflect adult age-at-death, as reduced mobility is often associated with increasing age. This hypothesis was tested by extracting geometric morphometric data from 200 adult femoral midshaft cross-sections originally harvested by M.F. Ericksen from The George Washington University dissecting-room cadavers. The sample was composed of 97 males and 103 females largely of European descent, ranging in age from 30 to 97 years (mean=71 years, standard deviation=12 years). A quantitative evaluation software was utilized to extract the periosteal outlines from oriented bitmap images of the femoral cross-sections, quantify the contour shapes with elliptic Fourier descriptors, and perform principal component analysis to summarize the shape information.

Although the results illustrated observable differences among the sample of femoral cross-sections, shape variance was not found to be significantly correlated with age. Specifically, none of the seven first principal components, accounting for 95% of the variance, correlated with age after a Bonferroni adjustment. The first principal component (representing an anterior-posterior flattening of the section and accounting for 63% of the total variance) was found to be significantly correlated only with the biomechanical properties, such as I_x/I_y and I_{\max}/I_{\min} , that are themselves different indicators of shape. Only PC3 and PC4 (accounting for a total of 7% of the variance) were statistically linked with sex (males display a rounder shape). Overall, these findings reinforce how femoral midshaft shape primarily reflects mechanical environment regardless of age and suggest there is too much variation in mobility among this sample of modern humans for femoral shape to be a useful indicator of age-at-death.

Age-at-Death, Geometric Morphometrics, Elliptical Fourier Analysis

A54 **Body Height Estimation From Femur Measurements in Postmortem Computer Tomography**

Sandra Lösch, PhD, University of Bern, Institute of Forensic Medicine, Dept of Physical Anthropology, Sulgenauweg 40, Bern 3007, SWITZERLAND; Simon Kramis, MA, University of Bern, Institute of Forensic Sciences, Dept of Physical Anthropology, Sulgenauweg 40, Bern 3007, SWITZERLAND; Maya Näf, MA, University of Bern, Dept of Forensic Medicine and Imaging, Bühlstrasse 20, Bern 3012, SWITZERLAND; Frank Siegmund, PhD, Heinrich Heine University Düsseldorf, Universitätsstr. 1, Düsseldorf 40225, GERMANY; Fabian Kanz, PhD, Department of Forensic Medicine, Sensengasse 2, Vienna 1090, AUSTRIA; and Wolf-Dieter Zech, MD, University of Bern, Institute of Forensic Medicine, Dept of Forensic Medicine and Imaging, Bühlstrasse 20, Bern 3012, SWITZERLAND*

After attending this presentation, attendees will: (1) understand how body height from computed tomography data can be estimated; and, (2) gain knowledge about the accuracy of estimated body height and limitations.

The presentation will impact the forensic science community by providing knowledge and competence which will enable attendees to develop formulas for single bones to reconstruct body height using postmortem Computer Tomography (p-CT) data.

The estimation of Body Height (BH) is an important component of the identification of corpses and skeletal remains. Stature can be estimated with relative accuracy via the measurement of long bones, such as the femora. Compared to time-consuming maceration procedures, p-CT allows fast and simple measurements of bones. This study undertook four objectives concerning the accuracy of BH estimation via p-CT: (1) accuracy between measurements on native bone and p-CT imaged bone (F1 according to Martin 1914); (2) intra-observer p-CT measurement precision; (3) accuracy between formula-based estimation of the BH and conventional body length measurement during autopsy; and, (4) accuracy of different estimation formulas available.¹

In the first step, the accuracy of measurements in the CT compared to those obtained using an osteometric board was evaluated on the basis of eight defleshed femora. Then the femora of 83 female and 144 male corpses of a Swiss population for which p-CTs had been performed, were measured at the Institute of Forensic Medicine in Bern. After two months, 20 individuals were measured again in order to assess the intraobserver error.

The mean age of the men was 53 ± 17 years and that of the women was 61 ± 20 years. Additionally, the body length of the corpses was measured conventionally. The mean body length was 176.6 ± 7.2 cm for men and 163.6 ± 7.8 cm for women.

The images that were obtained using a six-slice CT were reconstructed with a slice thickness of 1.25 mm. Analysis and measurements of CT images were performed on a multipurpose workstation. As a forensic standard procedure, stature was estimated by means of the regression equations by Penning & Riepert developed on a Southern German population and for comparison, also those referenced by Trotter & Gleser "American White."^{2,3} All statistical tests were performed with a statistical software.

No significant differences were found between the CT and osteometric board measurements. The double p-CT measurement of 20 individuals resulted in an absolute intra-observer difference of 0.4 ± 0.3 mm.

For both sexes, the correlation between the body length and the estimated BH using the F1 measurements was highly significant. The correlation coefficient was slightly higher for women. The differences in accuracy of the different formulas were small. While the errors of BH estimation were generally ± 4.5 – 5.0 cm, the consideration of age led to an increase in accuracy of a few millimetres to about 1 cm. BH estimations according to Penning & Riepert and Trotter & Gleser were slightly more accurate when age-at-death was taken into account.^{2,3} That way, stature estimations in the group of individuals older than 60 years were improved by about 2.4 cm and 3.1 cm.^{2,3} The error of estimation is therefore about a third of the common ± 4.7 cm error range.

Femur measurements in p-CT allow very accurate BH estimations. Estimations according to Penning led to good results that (barely) come closer to the true value than the frequently used formulas by Trotter & Gleser "American White."^{2,3} Therefore, the formulas by Penning & Riepert are also validated for this substantial recent Swiss population.

Body Height, Postmortem Computer Tomography, Femur Measurement

A55 Comparative Performances of Sacral Osteometrical and Geometric Morphometrical Studies Based on Multi-Slice Computed Tomography Explorations to Assess Sexual Dimorphism

*Marion Vergnault**, Hôpital De Rangueil, 1 Avenue Du Professeur Jean Poulhès, Tsa 50032, Toulouse 31059, FRANCE; *Frederic Savall*, Service de médecine légale, Hopital de Rangueil, 1 avenue Professeur Jean Poulhès, Toulouse Cedex 9 31059, FRANCE; *Fabrice F. Dedouit*, 1 Avenue Du Professeur Jean Poulhes, Toulouse Cedex 9, FRANCE; *Hervé Rousseau*, PhD, 1 Avenue Professeur Jean Poulhès, Toulouse 31059, FRANCE; *Daniel Rouge*, MD, Service de Medecine Legale, Centre Hospitalier Univ Rangueil, Avenue du Professeur Jean Poulhes, Toulouse Cedex 4 31403, FRANCE; and *Norbert Telmon*, PhD, MD, Service Medico-Judiciare, CHU Rangueil, 1 Avenue Jean Poulhes, Toulouse F-31054, FRANCE

After attending this presentation, attendees will become familiar with different statistical methods that can be used to estimate sacral sexual dimorphism from multi-slice computed tomography data. This presentation will present classic and original multivariate analyses based on metric data and a geometric morphometric analysis.

This presentation will impact the forensic science community by showing classification and segmentation trees as an alternative statistical tool to classic multivariate analysis for sex determination in anthropological research, with results similar to geometric morphometric analyses.

Sex estimation from skeletal remains for identification is an important component of many anthropological investigations. Sacrum, due to its contribution to the pelvic girdle, demonstrates sex differences. This sacral sexual dimorphism is classically studied by using multivariate analysis on metric data. Geometric morphometric analysis is another pertinent approach widespread in anthropological research to study sexual dimorphism.

The present study seeks to compare two statistical methods using classic published metric parameters and geometric morphometric analysis for sacral sex estimation based on multi-slice computed tomography.

A total of 13 landmarks were located on sacral multi-slice computed tomographies of 174 individuals (86 males and 88 females). Fourteen variables (seven distances and seven indices) were selected from the literature for their effectiveness in sex determination.

First, a univariate analysis using t-tests was performed on all. Then multivariate statistics, including Linear Discriminant Analysis (LDA) and classification trees, were realized from variables that showed a significant sexual difference in the univariate analysis. A geometric morphometric analysis was realized from the 13 landmarks and a Canonical Variate Analysis (CVA) was performed from procrustes landmarks coordinates.

The accuracy rate for sex assessment using LDA was 81.3% from five distances and 79.4% from five indices. Sex predict yielded 85% with classification and segmentation tree using four metric parameters (three distances and one indice). The CVA results based on the 13 procrustes landmarks coordinates showed a correct classification for 87.9% of the individuals.

These results were in accordance with previous studies about sacral sex assessment. Classification and segmentation trees showed better results than linear discriminant analysis and similar results to geometric morphometric analysis, but used only four parameters. Classification and segmentation tree seems to be a pertinent and easily alternative statistical tool to classical multivariate analysis for sex determination in anthropological research.

This study revealed that geometric morphometric analysis did not demonstrate a more objective superiority in sacral sexual determination than anthropometric analyses. Moreover, this study provided a particular application of virtual anthropology by transposing classical metric parameters studied on dry bones to multi-slice computed tomography.

Sexual Dimorphism, Classification Trees, Geometric Morphometrics

A56 Sex Estimation Using Discriminate Function Analysis of Non-Metric Cranial Traits: An Inter-Observer Error Study

*Janna M. Andronowski, MSc**, 250 S Stadium Hall, Knoxville, TN 37917; *Kyle A. McCormick, MA*, 824 W Hill Avenue, Apt 301, Knoxville, TN 37902-3015; and *Michael W. Kenyhercz, MS*, University of Alaska Fairbanks, 403 Salcha Street, 310 Eielson Bldg, Fairbanks, AK 99775

The goal of this presentation is to explore inter-observer error rates of sexually dimorphic non-metric cranial traits using the Walker five-trait scoring system.

This presentation will impact the forensic science community by providing further treatment to inter-observer error rates for non-metric cranial traits. While Walker assessed inter- and intra-observer error rates for sexually dimorphic cranial traits, the sample size was small ($n=10$) and the confounding variables of observer interaction and observer experience were not partitioned out from this assessment.¹ The current study attempts to evaluate inter-observer error derived from the scoring method by controlling for experience level.

Skeletal sex estimation is traditionally based on the subjective morphological assessment of traits of the pelvis and skull. To standardize morphological assessment, Walker developed a five-trait scoring system to evaluate the expression of non-metric cranial sex traits. The traits include the supraorbital margin, the mastoid process, the supraorbital ridge/glebella, the nuchal crest, and mental eminence. Each trait is scored on a scale of 1 to 5, which shows the progression of the traits from gracility (1) to robust (5).

Minimal treatment has been given to inter-observer error rates for visually scored traits of the skull. As such, the objectives of this study are to: (1) evaluate inter-observer error derived solely from the original scoring method as proposed by Walker; and, (2) assess how inter-observer error affects sex estimation.

The current work evaluates a large sample of individuals of known age and sex ($n=78$; $F=37$, $M=41$) using the Walker five-trait scoring system. Data were obtained from the William M. Bass Donated Skeletal Collection housed at the University of Tennessee, Knoxville. Ages range from 24 to 88 years old. Each of the traits was scored in accordance with Walker.¹ The left side was evaluated in the event of paired traits. Trait scores were compared among three anthropologists with similar levels of experience to negate error attributed to varied levels of experience. As such, any variation in scores among observers can be ascribed to inherent limitations in the scoring method as opposed to differences in experience level.

Statistical software was used to perform Fleiss' Kappa, the Intra-Class Coefficient (ICC) and Discriminant Function (DF) analyses.² The ICC was applied to account for close observations between observers and was used with a two-way model that evaluated both consistency and absolute agreement. Trait score differences among observers were assessed and subsequently compared to those reported by Walker.¹

Results indicate that, for most traits, there is consistent scoring agreement among observers. The majority of the traits showed substantial absolute agreement (>0.7) with the exception of the mental eminence, which showed a moderate agreement of 0.54. Further, the observations were substantial to almost perfectly consistent between anthropologists.

Agreement between observers was the same for each DF at approximately 72%. In cases of disagreement, sex bias was idiosyncratic to the observer. A score of 1 for female and -1 for male was assigned to each disagreeing observer's sex estimation. Observer Three had a sex bias score of -10, or a strong male bias. Observer Two had a sex bias score of 13, or a strong female bias. Observer One had a sex bias score of 2, or no appreciable sex bias. Though the DF identified a sex bias in two of the three observers, correct classifications of sex were not impacted by the observer bias as each scorer showed correct classifications higher than 77%.

The current study provides further treatment to inter-observer error rates for non-metric cranial traits. Though results indicate that there is some subjectivity associated with the scoring system, trait scores can be reliably assigned by observers with comparable levels of experience. Thus, when possible, sex estimation from the skull should be confirmed through blind peer review.

In contrast to inter-observer error results reported by Walker, the majority of traits scored revealed substantial absolute agreement among observers.¹ As such, by controlling for observer experience level, the inter-observer error inherent in the scoring system is quite low.

Inter-Observer Agreement, Cranial Non-Metrics, Sex Estimation

A57 Comparing Cranial Morphology in Asian and Hispanic Populations: Exploring Why Misclassification Can Occur When Using Discriminant Function Analysis

Beatrix Dudzik, MA, 3909 Briargate Avenue, Knoxville, TN 37919*

After attending this presentation, attendees will have baseline knowledge of the similar and distinct cranial morphologies that are represented among various modern Asian and Hispanic samples.

This presentation will impact the forensic science community by providing quantification of size and shape variables of the human cranium among the aforementioned populations in an effort to elucidate why misclassification of Asian and Hispanic individuals can occur when performing discriminant function analyses between these groups.

Arguably one of the most difficult and daunting tasks that forensic anthropologists face during the construction of the biological profile, is the estimation of ancestry. The interaction between heritability and the influence of environmental factors which result in the common microevolutionary forces outlined in the literature is not a cause-and-effect relationship and thus will continuously provide research fodder for a range of disciplines that seek to examine how human populations adapt and change over time. Practitioners that work within the unique context of North America, which has high percentages of populations from all over the world and is often referred to as a genetic and biological melting pot, must be especially cognizant of these factors when estimating ancestry of unidentified individuals. Specifically, it has been reported by forensic anthropologists who operate in the American Southwest that using reference samples provided by FORDISC® 3.0 software can misclassify Hispanic individuals as representative of modern Japanese and other Asian populations.¹

To examine the morphological overlap that can occur when attempting to estimate ancestry of Hispanic and Asian skeletons, this study employed discriminant function and canonical variate analysis to examine morphological differences and similarities among the populations sampled. Fifteen standard cranial measurements were used that represent all developmental and functional modules of the human cranium. The Asian samples used included male and female individuals from Korea (n=52), China (n=60), Vietnam (n=45), Thailand (n=109), and Japan (n=240). The University of Tennessee Forensic Databank provided the Korean and Vietnamese samples, while the Japanese, Thai, and Chinese samples were measured for this study. The Japanese samples are representative of northern, middle, and southern Japan and were collected from Sapporo University, Tohoku University, University of Tokyo, Kyoto University, Kyushu University, and University of the Ryukyus, respectively. The Thai sample was collected at Khon Khaen University and the Chinese sample was collected at Hong Kong University. Additionally, the Hispanic data (n=450) was provided by the Forensic Databank.

Results indicate that, in general, good separation between the Hispanic and Asian samples described can be achieved with discriminant function and canonical variate analysis. Specifically, while it has been found that misclassifications of Hispanic individuals occur at a higher rate among the Japanese than any other Asian population sampled, it was shown in this study that significant differences can be identified within the cranial vault. In particular, Hispanic samples were shown to be much wider within the posterior portion of the cranium, while the anterior portion of the vault were shown to be much narrower than the Japanese samples; however, considerable overlap was also found among the Japanese and Hispanic samples in many of the other cranial dimensions represented by the measurements used, indicating that misclassification is indeed easy to achieve. In regard to the other samples used, it was found that, in general, the Asian samples clustered together and were distinct from the Hispanic samples, but separation was also identified between the East Asian and Southeast Asian individuals. Morphological distinction was also identified that separates the Japanese samples from the other Asian samples in some dimensions of the cranium.

The patterns observed in this study show that morphological similarities and distinctions can be identified when comparing Hispanic samples to East and Southeast Asian populations. While overlap is observed among the Asian and Hispanic samples, there are also specific regions of the cranium, namely anterior and posterior portions of the vault, where differences are identified, particularly among the Hispanic and Japanese samples. Thus, this indicates that partitioning the cranium and using specific dimensions may increase accurate ancestry estimation. This information may provide anthropologists with a better understanding of cranial variation in Hispanic and Asian populations that may ultimately result in more accurate estimates of the biological profile and in a higher percentage of positive identifications.

Cranial Morphology, FORDISC®, Forensic Anthropology

A58 Quantification of Frontal Sinus Morphology From Radiographs for Positive Identification

Priyanka Atit, BA, C.A. Pound Human Identification Laboratory, Cancer & Genetics Research Complex, 1376 Mowry Road, Rm G-17, Gainesville, FL 32610; Carlos J. Zambrano, MS, Cancer/Gen Resarch Complex, 2033 Mowry Road, PO Box 103615, Gainesville, FL 32610; and James D. Pampush, MS, University of Florida, Dept of Anthropology, Turlington Hall, Rm 1112, Gainesville, FL 32611*

After attending this presentation, attendees will possess a general understanding of the key challenges facing forensic anthropologists in determining identity using frontal sinus radiographs. This study highlights an alternative and easily accessible method of metric analysis of the frontal sinus.

This presentation will impact the forensic science community by investigating a quantitative method for establishing positive identification of an unknown individual using frontal sinus form.

Human frontal sinuses are lobate cavities contained within the frontal bone; their morphology is evident on radiographs and they remain consistent over the adult lifespan. Prior research has attempted to use the frontal sinus for forensic identification, for which methodology is expected to adhere to the *Daubert* guidelines. The *Daubert* guidelines govern the admissibility of scientific evidence in the federal court system and require standardized methodology to have acknowledged limitations and a replicable technique. Earlier studies have successfully used the frontal sinus to identify individuals; however, the subjectivity of the methods does not meet the *Daubert* standards. The research presented here is an attempt to develop frontal sinus identification methodologies that meet the *Daubert* guidelines. Moreover, this study follows recent efforts to quantitatively assess the frontal sinus and the goal is to develop a simple analytical method that can be used on commonly accessible software (e.g., ImageJ[®], R, and MS[®] Excel[®]).

For this study, 40 cranial radiographs with frontal sinuses meeting the selection criteria were randomly chosen from the C.A. Pound Human Identification Laboratory case archives. Using ImageJ[®], the scale was independently calibrated for each radiograph and a lower boundary line was drawn to demarcate the sinus. Area, perimeter, width, height, and circularity measurements were obtained by tracing the superior margin of the sinus. Each of the cranial radiographs were then traced four times — twice each by two separate observers to test for both inter-observer and intra-observer error. To test the applicability of this method for antemortem vs. postmortem identification, a four-crania demonstration sample was generated by radiographing each crania twice; once with a bag of substrate under the cranium to produce noise in the “antemortem” radiograph, and then without the substrate to represent a postmortem image. Single blind tracings by were used to examine if an antemortem image could be correctly matched to its postmortem counterpart with the described measurements.

Intra- and inter-observer error were tested using paired *t*-tests and Pearson’s correlations. The paired *t*-tests suggest that frontal sinus measurements are consistent and repeatable by observers who have practiced the tracing method. Pearson’s correlations (r^2 -values > 0.860) indicate good congruency of measures between observers. Measurements from the original 40 tracings were Z-score scaled, and Euclidean distances between three sets of measures were calculated: (1) distances between individuals measured twice by the same observer; (2) distances between individuals measured twice by two different observers; and, (3) distances between random pairings of individuals. *T*-tests on Euclidean distances demonstrate matched individuals to be significantly closer than randomly paired individuals. Furthermore, gamma distributions calculated from the Euclidean distance sets allowed for the generation of log-likelihood ratio values. Matched individuals’ Euclidean distances consistently showed positive log-likelihood ratio values compared to randomly paired individuals, demonstrating quantitative reliability. Using Euclidean distance measures and the log-likelihood ratios, three of the four crania in the demonstration sample were positively identified. Measurement error associated with the height measure for one of the “antemortem” images precluded positive identification for this individual. Euclidean distances from all four random pairings of the demonstration sample indicated no-matches.

Anthropology Section - 2015

Although these preliminary results indicate that quantifying frontal sinus morphology can be accomplished with readily available software, there are some limitations to this method. For tracing simplicity, only individuals with connected sinuses were used. As such, features that could be used for individualization (e.g., separate sinus cavities, partial septa, etc.) are not captured in the presented method. Future studies should focus on expanding the sample size and enhancing the method by quantifying and incorporating more individualizing features. By excluding such diagnostic features, the individualizing power of frontal sinus morphology for identification purposes is constrained. Ultimately, while somewhat limited, the research presented here demonstrates a quantitative technique for using frontal sinus morphology in forensic identifications following the *Daubert* guidelines.

A59 An Outline Analysis of Ancestry and Sex Differences in Cranial Shape

Rachel E. Murphy, BA, 100 W Canopy Oak Court, Apt 2B, Cary, NC 27513; and Heather M. Garvin, PhD, Mercyhurst University, Dept of Applied Forensic Sciences, 501 E 38th Street, Erie, PA 16546*

The goal of this presentation is to introduce a new approach to the estimation of sex and ancestry from skeletal remains as a part of the formation of a biological profile. Attendees will understand the utility of cranial outlines in the estimation of ancestry and sex from the skull. Further, attendees who are accustomed to visually analyzing non-metric traits will learn that geometric morphometric outline analysis can also capture the overall variation in trait expression and help identify cranial traits that are responsible for the most variation between ancestry and sex groups.

This presentation will impact the forensic science community by introducing a new method for studying human cranial variation that is capable of increasing the objectivity of traditional non-metric techniques used to estimate the biological profile from skeletal remains.

Forensic anthropological techniques that utilize non-metric skeletal traits to estimate sex and ancestry have historically been criticized for their subjectivity and replicability; however, non-metric traits have proven to be valuable tools in identifying remains in forensic investigations. In this study, geometric morphometric analyses of cranial outlines (lateral, posterior, and superior views) were performed to assess population and sex variation in a sample of modern humans. 3D scans of 198 crania were collected from the Hamann-Todd and Terry skeletal collections. 2D images of the left lateral, superior, and posterior outlines were subsequently captured from these scans. These three views were chosen for analysis because they are most likely to capture the variation of cranial traits traditionally used to estimate sex and ancestry, such as glabella projection, frontal bossing, dolichocephaly, and facial prognathism. Elliptical Fourier analysis was utilized to define the cranial outlines and principle component analysis was performed on the elliptical Fourier descriptors to quantify shape variables into uncorrelated numerical values. Two-way Multivariate Analysis of Variance (MANOVA) analyses were performed on the principle components to test for sex and ancestry differences in outline shape. Two-way Wilk's lambda discriminant function analyses were also performed to determine the utility of these cranial outlines in discriminating between sex and population groups.

Results indicate that cranial outlines are able to differentiate between American Blacks and Whites, as well as American males and females, with high accuracy. Discriminant function analysis performed on the lateral view between Blacks and Whites performed extraordinarily well, resulting in a 92.4% cross-validated correct classification. The first principle component (39.8%) appears to reflect changes in vault shape (brachiocephalic vs. dolichocephalic) and degree of maxillary prognathism. These results support the traditional hypothesis that Black individuals tend to have a more elongated cranial vault and more prognathic face, while White individuals tend to have more rounded crania with less prognathism. The lateral view was also the best at differentiating between males and females. Principle component four, which only accounted for 5.53% of the variation within the sample, actually performed the best when differentiating between the sexes. The shape changes occurring in this principle component include glabella projection, with males possessing larger, more pronounced glabellae than females. Overall, results indicate that significant sex and population differences in cranial shape do exist and follow traditional qualitative descriptions. Outline analysis may provide a more objective means of estimating sex and ancestry from these traits, thereby increasing estimation accuracy (as high as 93% between ancestry groups).

Forensic Anthropology, Morphometric Outline Analysis, Non-Metric Traits

A60 Stature Estimation Using the Mandible in a Caucasian Italian Population

Chantal Milani, DMD, MS, Forensic Odontology & Anthropology Office, Via Madama Cristina, 94, Turin, Piedmont 10126, ITALY; Andrea Evangelista, MS, Unit of Clinical Epidemiology, Città della Salute, Via Santena, 7, Torino 10126, ITALY; and Gian Luigi Panattoni, MD, University of Torino, C.so Massimo D'Azeglio, 52, Torino 10126, ITALY*

After attending this presentation, attendees will have additional analytical tools for assessing unknown human remains. A new method for estimating stature using the mandible will be introduced, particularly useful where few diagnostic skeletal elements are present.

This presentation will impact the forensic science community by providing a new method to contribute to the biological profile using a skeletal element not typically used for this purpose. When unknown human skeletal remains are recovered, anthropologists estimate the biological profile (age, sex, ancestry, stature, etc.) using all available analytical tools. In this way, it is possible to reduce the list of potential missing persons matches and to help achieve a positive identification.

In forensic anthropology, stature estimation is an important parameter used in personal identification where the most common methods involve analysis of the full skeleton or long bones.^{1,2} If long bones are absent, the only remains available may be ones not normally used to estimate stature. The mandible is potentially valuable in connection with stature estimation, but has been little studied, despite its successful use in estimating sex and, in some cases, age. Since stature is population-specific, a mandible-based method should derive from study of a population biologically similar to the remains being analyzed.³ A stature method based on the mandible in a Caucasian Italian population is still not present in the current literature.

The current study investigated the relationship between the mandible and the stature of individuals from a Caucasian Italian population in order to develop a formula for the estimation of stature from this bone. The sample included 103 living Caucasian individuals from Italy (62 males and 41 females) with a mean age of 41.4 years. The variables of interest include four mandibular parameters (total condylar width (CoCo), total gonial width (GoGo), Condylar-Gonion (CoGo), and Gonion-Gnation (GoGn)) as well as measured stature (cm), age of the individual, and ancestral information (to confirm ancestry).

Using the data collected, Mean Stature (Hcm) was modeled using linear regression models. In the literature, previous models establish the relationship of Hcm with sex and age (e.g., it is known that stature decreases with age).⁴ Therefore, these two variables (sex and age) were included in the linear regression models in addition to the measurements of the mandibular parameters using two different approaches:

Model A - Including a parameter called "Outline": $2*(CoGo+GoGn)$.

Model B - Including all the singular parameters (CoCo, GoGo, CoGo, and GoGn) and reducing their number on the way by means of a backward selection. The final model included only parameters with a P value less than 0.10.

In both models (A and B), sex and age were strongly associated ($p < 0.01$) with stature, confirming Hcm is significantly higher in male and decreases with age. In Model A, this study found that Hcm was positively associated with the "Outline" ($p < 0.001$) resulting in a total model R^2 (coefficient of determination) of 0.657. Model B, after the backward selection, included as mandibular parameters CoGo ($p = 0.091$) and GoGn ($p < 0.001$), resulting in an R^2 of 0.665 for the final model.

In conclusion, based on R^2 value, the mandible appears to be potentially useful for stature estimation. In the current literature, similar R^2 value has been considered reliable when long bones are not available.⁵

The next stage of this study should be to validate these models using new mandibular and long bone measurements for Caucasian Italians. This method could be applied to improve personal identification of incomplete human remains in order to evaluate a range of stature for filtering the list of missing persons in a Caucasian Italian population.

Stature, Mandible, Identification

Anthropology Section - 2015

A61 Testing Inter-Observer Reliability of the Transition Analysis Aging Method on the William M. Bass Forensic Skeletal Collection

*Christina L. Fojas, MS**, University of Tennessee, Dept of Anthropology, 250 S Stadium Hall, Knoxville, TN 37996; *Jieun Kim, MA**, 250 S Stadium Hall, Knoxville, TN 37996; *Jocelyn D. Minsky-Rowland, MA**, University of Tennessee, Dept of Anthropology, 250 S Stadium Hall, Knoxville, TN 37996; and *Bridget F.B. Algee-Hewitt, PhD*, Stanford University, Rosenberg Lab, Dept of Biology, Gilbert Bldg, Rm 109, 371 Serra Mall, Stanford, CA 94305-5020

After attending this presentation, attendees will gain an understanding of the Transition Analysis (TA) component-scoring and age-estimation method and its applicability in a modern, forensic skeletal collection.

This presentation will impact the forensic science community by providing method-validation information for the repeatability and teachability of the TA method by assessing the degree of variation in age estimates produced from differently assigned scores.

Age estimation is an integral part of the biological profile generated by forensic anthropologists presented with a set of unidentified skeletal remains. For nearly a century, scholars have investigated age-related changes to the adult skeleton with varying degrees of success. It is generally understood that accurate and precise age-at-death estimates derive from the evaluation of multiple anatomical elements and skeletal traits (or components) within an anatomical element rather than isolated, single-age indicators. Multiple-trait approaches better capture the sequential aging process that occurs at different rates among individuals and, therefore, provide a more reliable age estimate. The TA age-estimation method of Boldsen and colleagues is one such component scoring system.¹ This method utilizes skeletal observations of the pubic symphysis, auricular surface, and cranial sutures to make inferences about the timing of transitions of specific osteological traits from one stage to the next. The transitional ages derived from skeletal traits are then inverted using Bayes theorem in combination with prior knowledge on the age-at-death distribution of the target in order to calculate maximum likelihood estimates and 95% confidence intervals. Boldsen et al. urged others to validate the TA method and, in the last decade, several studies have responded to this call.²⁻⁵ The current study seeks to contribute to this discourse and is the first inter-observer error study using TA with more than two observers. Specifically, inter-observer error tests among practitioners representing varying levels of TA scoring experience have been carried out in an effort to assess its applicability to achieve accurate age-at-death estimates.

The sample data consist of 58 positively identified cases from the William M. Bass Forensic Skeletal Collection curated at the University of Tennessee, Knoxville. The Bass Forensic Collection is a skeletal collection of 20th- and 21st-century Americans. Five researchers independently applied the TA method as described by Boldsen et al. to the available elements with no prior knowledge of chronological age. These scores were input into the software and maximum likelihood estimates and 95% confidence intervals attained using the United States homicide prior distribution. To evaluate inter-rater reliability and agreement of the raw scores, Krippendorff's alpha values were calculated for each trait using R. Unlike other specialized coefficients such as Cohen's or Fleiss's Kappa, Krippendorff's alpha is a generalization of a number of reliability indices and allows for more than two observers, any measurement level, small sample sizes, and incomplete or missing data.⁶ Alpha values close to one denote increased reliability while values nearing zero signify less reliable measures.

Krippendorff's alpha values indicate that the majority of traits had a moderate to excellent agreement among observers with a 0.6 or better level of agreement. For a single trait, superior surface morphology had the least amount of congruence (0.355) and the ventral symphyseal margin had the most congruence among scores (0.903). A repeated measure Analysis of Variance (ANOVA) demonstrates that, despite differences among the five raters with regard to knowledge of the TA method, there are no statistical differences between the maximum likelihood ages estimated by each observer and the true ages. These results indicate that the TA method can be reliably used by researchers of varying experience levels to estimate the age of an unknown individual.

Forensic Anthropology, Biological Profile, Age-at-Death

Anthropology Section - 2015

A62 Obliteration of Sharp Force Trauma Artifact by High Particulate Water Wash

Avery J. Appleton*, University of New Haven, 300 Boston Post Road, Forensics Ste, West Haven, CT 06516; and R. Christopher O'Brien, PhD, University of New Haven, Dept of Forensic Science, 300 Boston Post Road, West Haven, CT 06516

After attending this presentation, attendees will understand: (1) the taphonomic processes occurring in marine and aquatic environments; (2) the abrasive effect that suspended particulate has on bone and sharp force trauma wounds existing on bone; and, (3) the applicability of this information in the forensic science field.

This presentation will impact the forensic science community by providing information about specific morphological changes that occur when injured bones are left submerged in water for extended periods of time as well as estimation of time-since-deposition, trauma site identification, and associating remains with a particular event.

Forensic examination of bone is not always a straightforward enterprise. A complex interplay of factors contribute to the information able to be gleaned from a set of skeletonized remains that is largely influenced by the environment in which the remains were found. Bone weathering has been well studied and documented regarding skeletonized remains in terrestrial environments; however, less work has been published on the process of abrasion to bones that are submerged in particulate-laden dynamic water.

Skeletal material under water is subjected to a different set of stresses than in a terrestrial setting and research to fully document these postmortem changes is therefore required. Increasing instances of maritime disasters, such as the sinking of the Italian cruise ship *Concordia*, the loss of migrant boats in the Mediterranean and Timor Sea, as well as the recent loss of a ferry in South Korea, warrant further investigation of the processes of degradation of human remains found in marine environments as a result of both water flow and abrasion by suspended particulate matter. Studying the physical changes that occur over time to bones that may have been injured in a traumatic event such as a shipwreck can provide useful information to investigators, as information regarding time-of-death is often crucial to an investigation. This study seeks to determine if and how suspended particulate abrades identifiable characteristics of bone.

Pig (*Sus scrofa*) ribs were inflicted with sharp force trauma wounds using a meat cleaver and were then subjected to an environment simulating an underwater decompositional site using a high-particulate water wash in two different apparatuses. One model created bi-directional wave action via a rotational tumbler system in which the water and particulate were passed back and forth over the sample bones. The other model imitated uni-directional wave action using a circular track to wash a continuous wave over the sample bones. Uniform-grain sand and diatomaceous earth — comprised of the microscopic remnants of dead diatoms — were used separately as suspended particulate to mimic the sediment that is present in a marine environment. Samples were allowed to abrade for set intervals of time and examined using micrometer caliper and stereomicroscopy. These measurements were then inputted into a database, where statistical software was used to run Analysis of Variance (ANOVA) tests in order to determine significant differences. Regression analysis was conducted to determine the relationships between the rates of ablation and associated skeletal measurements.

Marine Taphonomy, Skeletal Abrasion, Forensic Anthropology

A63 Estimating the Postmortem Interval: A Validation Study of the Total Body Scoring Method Using Medicolegal Cases From Southeast Texas

Derek A. Boyd, BA*, California State University, Chico, 400 W First Street, Chico, CA 95929

After attending this presentation, attendees will understand the limitations of applying the Total Body Scoring (TBS) method to time-since-death estimates in cases of temperature-regulated indoor decomposition in humid environments.

This presentation will impact the forensic science community in terms of performance by contributing to the existing anthropological literature on the utility and contribution of the TBS to time-since-death estimations.

Time-since-death estimation often falls under the purview of the forensic anthropologist, requiring an extensive analysis of the intrinsic and extrinsic factors that affect decomposition. Methods employed in the estimation of time-since-death must be rigorously tested to ensure they are accurate, reliable, and contribute meaningful information to the death investigation. A common practice used by forensic anthropologists is to estimate the Postmortem Interval (PMI) based on the gross presentation of the decedent. Following this practice, Megyesi and colleagues attempted to correlate various stages of decomposition with Accumulated Degree Days (ADD).¹ They developed a standardized scoring system for the progression of decomposition, termed TBS, and found a strong positive correlation between estimated ADD and TBS. A regression formula that allowed the methods to be applied to medicolegal cases was developed for this study.

The TBS is considered to be one of the most reliable methods for quantitatively estimating time-since-death; however, several recent validation studies in various climate zones have found that the TBS method failed to produce reliable estimates. These studies cite humidity as a factor that may explain the variation seen in individual rates of decomposition. As a subtropical region, southeastern Texas experiences high levels of humidity year round, making this particular variable an important component of the decomposition process. For this reason, independent validation of the method for the specific environment is needed. Based on previous studies, the initial expectation for this study was that the TBS would yield time-since-death estimates incongruent with known PMIs.

For the present study, the TBS was applied retrospectively to medicolegal cases in which the decedent was found in a temperature-regulated indoor environment and had a documented last-seen-alive date. The study included 95 deaths investigated by the Harris County Institute of Forensic Sciences in Houston, TX, from 2013 to 2014. All cases had known PMIs of less than one year and temperature data recorded from indoor thermostat devices. Additionally, ambient temperature was recorded during the scene investigation and, when it deviated from the thermostat temperature, the average of the two temperatures was recorded. A TBS was assigned to each case using scene and autopsy photographs. In each case, the TBS was input into the regression formula developed by Megyesi and colleagues to calculate the total number of ADD and the associated standard error. Known and estimated ADD and associated PMIs were compared quantitatively. Accuracy was measured by dividing the number of cases with known PMIs within the estimated PMI ranges by the total number of cases in the sample. Additionally, eight individuals independently scored six cases to measure potential inter-observer error.

Overall, this study did not support the TBS in cases of temperature-regulated indoor decomposition in southeast Texas. The TBS accurately estimated the PMIs of 89 (94%) decedents, but yielded results with low specificity. There was no significant difference between mean known and estimated ADD ($U=4111.00$, $p=0.289$); however, there was a significant but weak positive relationship between assigned TBS and known ADD ($r=0.4576$, $p<0.001$). Additionally, a fixed-factors analysis of variance indicated that inter-observer error was low ($F=0.397$, $df=7$, $p=0.903$). These results suggest that, in the context of this study, the TBS fails to estimate the PMI with enough resolution to provide meaningful information to medicolegal death investigators; however, it does provide a quantitative means for comparing stages of decomposition between decedents. Further investigation into the utility of the TBS in estimating time-since-death in indoor environments is recommended.

Postmortem Interval, Total Body Scoring, Human Decomposition

A64 Bioreactors as a Method for Examining Environmental Effects of Changes in Bone Biochemistry Over Time

Melissa Dunphy, BS, 110 C Ole Towne Square, Clemson, SC 29630; Katherine E. Weisensee, PhD, Clemson University, Dept of Sociology & Anthropology, 132 Brackett Hall, Clemson, SC 29634; Elena Mikhailova, PhD, Clemson University, College of Agriculture, Forestry, & Life Sciences, 105 Sikes Avenue, Clemson, SC 29634; and Melinda Harman, PhD, Clemson University, Dept of Bioengineering, 105 Sikes Avenue, Clemson, SC 29634*

After attending this presentation, attendees will be familiar with novel techniques to design, develop, and maintain an artificial environment using interdisciplinary environmental databanks to systematically determine fundamental environmental parameters, specifically temperature and soil properties, as a method to determine these parameters' impact on bone biochemistry over time.

This presentation will impact the forensic science community by illustrating the potential of a reproducible artificial environment, a forensic bioreactor, which can be controlled over time to evaluate environmental parameters that impact chemical methods for determining the Postmortem Interval (PMI).

The universal application of novel methods for determining the postmortem interval, such as citrate concentration, hinge on a well-characterized understanding of the environmental parameters that impact bone biochemistry over time. The objective of this research is to design a forensic bioreactor that can quantitatively account for environmental parameters known to impact decomposition across a global environmental spectrum.

To accomplish this goal, a synergistic collaboration between several core disciplines was pursued. Bioengineering developed a controllable, artificial environmental system, forensic anthropology defined factors impacting bone decomposition, and soil science contributed knowledge and extensive data to determine environmental parameters. The specific objectives were: (1) to identify the environmental parameters that define a burial setting in an outdoor context that are also useful for forensic anthropology; (2) to discretize environmental parameters of an outdoor forensic burial setting using soil science databanks; and, (3) to design a functional forensic bioreactor that can be easily monitored and accurately mimic an outdoor burial setting.

In this study, the following environmental parameters were characterized: soil temperature, texture, soil horizon, soil depth, soil pH, and organic matter content. Soil temperature, soil organic matter content, and soil pH parameters were characterized using the online databank Web Soil Survey (WSS) and regional temperature and soil regime mappings. Four temperature regimes, two soil organic matter contents, and three soil pH values were selected. Soil analysis was conducted to quantitatively measure soil pH, texture, and the exact soil organic matter content. Soil depths were characterized using soil horizon data to simulate surface scatter and shallow grave burial, respectively. Bioreactor chambers were constructed using sterilized, thin-walled polystyrene boxes housed in calibrated temperature chambers. A total of 14 different environmental conditions were created and controlled successfully over a 90-day experiment.

This study describes an interdisciplinary approach to forensic anthropology and develops a forensic bioreactor system based on defined factors known to impact bone decomposition. Specifically, environmental factors important to forensic anthropology and useful for modeling decomposition in an outdoor context were defined and then discretized using soil science data. Finally, these factors were successfully incorporated into an easily monitored forensic bioreactor prototype that mimicked an outdoor setting. In this manner, the bone samples were treated as a tissue undergoing dynamic changes when exposed to a soil medium. This research provides a foundation for bone decomposition models and advances forensic anthropology related to determining PMI for skeletal remains. These results demonstrate successful implementation and control of forensic bioreactors simulating precise environments in a single research location, rather than testing in an outdoor context. Using this methodology, bioreactor systems can be created to replicate many different clandestine burial contexts, which will allow for more rapid understanding of environmental effects on skeletal remains.

Bioreactor, Postmortem Interval, Taphonomy

A65 The Effects of Decomposition Upon the Efficacy of Biometrics for Positive Identification

*Kelly Sauerwein**, University of Tennessee, Dept of Anthropology, 250 S Stadium Hall, Knoxville, TN 37996; *Tiffany B. Saul, MS**, 9919 Thunderbolt Way, Knoxville, TN 37923; *Dawnie W. Steadman, PhD*, University of Tennessee, Dept of Anthropology, 250 S Stadium Hall, Knoxville, TN 37996; and *Chris Boehnen, PhD*, Oak Ridge National Laboratory, PO Box 2008 MS-6075, Oak Ridge, TN 37831

After attending this presentation, attendees will understand: (1) the utility of biometrics for obtaining positive identification of unknown individuals; (2) the effects of decomposition on facial, iris, and fingerprint characteristics; (3) the necessary procedures for successfully obtaining these biometrics from human remains; and, (4) the types of predictions that can be made from these data.

This presentation will impact the forensic science community by describing the advantages and limitations of the use of biometric identifiers at early stages of decomposition.

Biometric identifiers are measurable, unique characteristics that are used to classify both living and deceased individuals. This study examines the effects of decomposition upon the ability to capture biometric information from three physiological characters: facial photographs, fingerprints, and iris scans. This study examines the maximum number of days in which usable biometric data can be successfully collected using digital technologies and how the recognition performance decreases over time. For the purposes of this study, *usable data* refers to images that are able to correctly identify the individual through a digital biometric program by matching the captured images with images taken upon the initial receipt of the donated individual. This study was conducted in conjunction with Oak Ridge National Laboratory and the University of Tennessee Anthropological Research Facility between the months of April and June. Digital facial photographs, iris scans, and fingerprints from the donated remains of eight (n=8) individuals were obtained daily until usable data could no longer be captured. The individuals were placed supine and mostly uncovered with the exception of wire mesh placed over the hands to prevent scavenger activity. The left iris of all individuals was hydrated with 0.4mL of sterile saline solution ten minutes prior to iris scanning to determine if this would increase the quality of images compared to the untreated right iris. No other preparations were made to the remains prior to data collection.

With daily high temperatures ranging between 59°F (15°C) and 84°F (28.89°C) during the spring trial (n=4), usable data was obtained for an average of four days. However, the early summer trial (n=4) included high temperatures between 81°F (27.22°C) and 91°F (32.77°C) and the number of days usable data could be captured was reduced to two. Overall, fingerprints proved to be the most reliable biometric data, producing usable data longer than iris scans or facial images (four days for fingerprints, two for facial, and one day for iris images). Insect activity, bloating, and color changes due to decomposition prohibited the capture of usable facial images after an average of two days (regardless of season), while dehydration, clouding, and collapse of the cornea prevented capture of usable iris scans after an average of two days in the spring and only one in the summer. Additionally, hydration of the left iris did not lead to an improvement in the quality of iris images when compared with the right iris.

This study demonstrated that digitally captured biometric data can be used within two to four days postmortem to identify individuals, compared to existing antemortem biometric data. For some modalities such as iris recognition, it has been generally believed, but never studied, that iris biometrics are only viable within the first 24 hours; however, the results of this study show that they remain viable for a longer period of time, depending upon environmental conditions. When scavenger activity is inhibited, fingerprints persist longer than facial and iris identifiers; however, temperature, precipitation, and insect activity were the primary factors affecting the retention of biometric information in decomposing human remains. While this study is an initial step in determining the utility of physiological biometric identifiers during the decomposition process, biometric research has the potential to make important contributions to forensic anthropology and the law enforcement, military, and medicolegal communities.

Biometrics, Human Decomposition, Positive Identification

A66 The Extraction of Handedness and Amount of Experience From Sawing Imprints in Bone

David T. Walta, MSc, Sonoystraat 55, The Hague, Zuid-Holland 2581VJ, NETHERLANDS*

After attending this presentation, attendees will be informed about the possibility of determining handedness and experience from sawing imprints. Attendees will learn the markers that need to be taken into account explained in a visual manner.

This presentation will impact the forensic science community by explaining how the usual tool mark examination is directed toward classifying the tool that was used. This research shows that characteristics of the perpetrator may also be extracted from the same trace. This will have an impact on the tool mark analysis in bone as it will add an extra dimension to this type of examination.

The research material for this examination was obtained with the help of volunteers. Each of the 38 volunteers provided three different sawing cuts in a sheep bone. All volunteers inflicted one shallow cut, one cut halfway through the bone, and one cut completely severing the bone. Thirty-one of the bones were examined for characteristics described in earlier research pertaining to sawing imprints. For handedness, extra care was given to the side on which these characteristics were more prominent. To determine experience, the general prominence, roughness, or smoothness of these same characteristics were examined. Additionally, anything that stood out or seemed to be a pattern was noted. The remaining seven bones were saved for a blind test.

In determining handedness, the downward direction of the sawing imprint was shown to be most related to handedness. The side of the cut on which flaring was most prominent, as well as the horizontal direction and the harmonics of the cut, were also related to handedness. Less important (but still somewhat indicative for handedness) were the roughness of the imprint walls, the striations in these walls, and the placements of false starts surrounding a main cut.

In order to analyze the bones in the case of experience, the amount of experience was quantified. This was done by asking the volunteers to rank themselves on a scale of one through ten, one being very inexperienced and ten being very experienced. In the case of experience, the roughness (or smoothness) of the floor and walls of the cut as well as their striations were indicative. The straightness of the walls and the vertical direction of the cut were also shown to be of value.

The reason for the changes in the sawing imprints was investigated. For handedness, it is argued that the most comfortable way of holding a saw is by tilting the blade. For left-handed people, this tilt will be the opposite of right-handed people, causing a difference in the placement or prominence of markers described in earlier research. For experience, it is argued that more experienced sawyers will start sawing more easily and will proceed evenly, causing smoother, straighter cuts.

The blind test was performed by examining the seven saved bones and using the stated markers to judge handedness and to estimate the amount of experience of the sawyer in question. In performing the blind test, handedness was correctly classified in five out of seven bones, one was inconclusive, and one was wrongly classified. For experience, the examination resulted in defining a range of experience (mostly of three digits). This range included the self-given score five out of seven times.

This research provides an indication that it is possible to extract information related to handedness and experience from a sawing imprint; however, this is research in a new area and is simply an indication. More research is needed, with larger sample sizes and more variables to justify and verify the conclusions drawn in this research.

Tool Marks, Handedness, Experience

A67 **Standardized Descriptive Method for the Anthropological Evaluation of Fractures of the Adult Neurocranium**

*Jason M. Wiersema, PhD**, Harris County Institute of Forensic Science, 1885 Old Spanish Trail, Houston, TX 77054; *Jennifer C. Love, PhD, OCME*, 401 E Street, SW, Washington, DC 22024; *Sharon M. Derrick, PhD*, Harris County Institute of Forensic Science, 1885 Old Spanish Trail, Houston, TX 77054; *Deborrah C. Pinto, PhD*, Harris County Institute of Forensic Science, 1885 Old Spanish Trail, Houston, TX 77054; and *Derek A. Boyd, BA*, California State University, Chico, 400 W First Street, Chico, CA 95929

The goal of this presentation is to provide case-example illustrations of a novel method developed for the standardized description of adult neurocranial fractures.

This presentation will impact the forensic science community by describing a method that is designed for use by anthropologists in the description of adult neurocranial fractures which circumvents the confounding effects of the inappropriate application of clinical fracture descriptions in the forensic context.

The system is a modification of the system recently presented for use with pediatric cases.¹ The presentation will: (1) describe the method; (2) place the method within the context of the existing skull fracture literature; and; (3) describe a validation study based on the application of the method to forensic casework examined at the Harris County Institute of Forensic Sciences (HCIFS).

Interpretation of head trauma is an important component of the forensic autopsy that benefits from thorough detection, standardized description, and appropriate interpretation of skull fractures. The majority of the literature pertaining to skull fracture is clinically based and thus motivated by the need for effective assessment of both fracture characteristics (type, frequency, location, and mechanics) and context (severity of injury, associated soft tissue damage, and patient prognosis). Much of the data pertaining to adult skull fractures is drawn from studies of traumatic brain injury. This clinical perspective is reflected in the significant array of skull fracture classification systems that exist. Most clinical schema identify some variation of the following fracture categories: simple, complex, compound, comminuted/composite, depressed, basilar, stellate, and diastatic. From a strictly descriptive standpoint, these categories are not mutually exclusive but instead represent overlapping levels of detail in fracture description that are useful in the clinical setting but confound the non-clinical description of fractures in the forensic context. For this reason, application of these schema in the forensic anthropological interpretation of skull fractures, as manifest on the bone itself rather than imaging/associated clinical findings, is inappropriate.

It is argued that forensic anthropological interpretation of adult neurocranial fractures requires a standard classification system that reflects fracture morphology alone; thus, a three-step classification system which conveys increasing detail with each additional step is suggested. The first, and most basic step is the fracture *category* of which four variations exist: simple, complex, comminuted, and hyper-fragmented. The second step describes the fracture *pattern*, e.g., linear, curvilinear, and stellate. The third step adds the fracture *descriptors*, e.g., depressed. Thus, the proposed system utilizes the fracture characteristics that covary with, but are not independent of, the basic fracture categories, as modifiers rather than additional fracture categories.

The proposed schema was applied retrospectively to evaluate its applicability and repeatability. The study sample included all HCIFS adults autopsied between January 1, 2011, and August 15, 2013, and who had the terms “fracture” and “cranium” or “skull” in the cause of death. Thirty-nine cases met the sampling criteria and were included in the study. For each case, four doctoral-level forensic anthropologists examined photographs taken during the autopsy and photographs of processed bone, when available. Each analyst described each fracture following the proposed schema. Intra-observer disagreement was evaluated.

The study was intended to: (1) statistically evaluate the effectiveness of the schema in capturing the variation in neurocranial fractures seen at the HCIFS; and, (2) to identify the potential for inter-observer error in the application of the schema. Forty-four fractures were found in the 39 cases. Application of the method demonstrated that the proposed schema adequately documented fracture variation in each of the cases and validated the effectiveness of the schema in describing fractures of the adult cranial vault. There was 100% agreement between the four anthropologists in the assignment of the fracture category. The fracture patterns assigned to each fracture were also highly consistent among the analysts, with only six of 156 discordant entries (3% error rate) between observers.

This study illustrates the value of the proposed schema for the standardization of the anthropological description of adult neurocranial fractures and the effective distinction of fracture description and clinical implication. The system is adequate for the anthropological classification of the majority of skull fractures observed during medicolegal autopsies of adults.

A68 Identifying Undocumented Border Crossers From the Texas-Mexico Border: A Collaborative Effort

Hailey A. Duecker, BA, 12108 Lavinia Lane, Austin, TX 78753; and Kate Spradley, PhD, Texas State University, Dept of Anthropology, 601 University Drive, San Marcos, TX 78666*

After attending this presentation, attendees will understand how the Forensic Anthropology Center at Texas State (FACTS), in collaboration with other universities, human rights organizations, and government offices, facilitate identifications from a humanitarian crisis along the Texas-Mexico border. Additionally, this presentation will highlight the mentoring of future forensic anthropological practitioners through these humanitarian efforts.

This presentation will impact the forensic science community by highlighting the various collaborative efforts and methodologies used to help identify and repatriate Undocumented Border Crossers (UBCs) from South Texas.

A high number of UBC deaths occur each year in Brooks County, TX (80 in 2011, 129 in 2012, and 87 in 2013); these deaths fall under the jurisdiction of a Justice of the Peace (JP), as there is no medical examiner within the county. Due to the dramatic increase in deaths and lack of resources, the local JP and Brooks County Sheriff's Office were overwhelmed with deaths and began to bury the UBCs, most without proper analyses or collection of DNA samples, leaving little chance for UBC identification and repatriation. During the summers of 2012 and 2013, Drs. Lori Baker and Krista Latham and their students performed voluntary exhumations of UBC burials within Brooks County for the purposes of skeletal analysis and DNA sampling in hopes of facilitating positive identifications. The purpose of this presentation is to describe the work of faculty and students at Texas State to identify and repatriate the remains of these individuals as well as to specify the external collaborations that are required for this humanitarian crisis.

The majority of the Brooks County exhumations contained individuals in early to late stages of decomposition, requiring a storage area or location for further decomposition until the maceration could be accommodated. Because the FACTS has large-scale storage and maceration capabilities due to the Forensic Anthropology Research Facility (FARF) and the Osteological Research and Processing Laboratory (ORPL), UBCs with significant amounts of flesh (47 in 2013 and 20 in 2014) were brought to the FACTS to await maceration and analysis. Once in the FACTS custody, all UBCs are taken to the FARF and placed in a special enclosure within the facility. The UBCs are not used in any decomposition or taphonomic studies at the FARF. During placement of UBCs at the FARF, faculty and staff conduct intake procedures that involve opening the body bags and documenting the condition of remains and personal effects. At this time, personal effects are removed and placed in plastic bags for freezer storage until they can be hand-washed and dried for photography.

All case information is entered into the National Missing and Unidentified Persons System (NamUs) and students search through the possible missing persons matches to narrow down potential identifications. DNA samples are sent to the University of North Texas for profiling and uploading into the Combined DNA Index System (CODIS). Clothing descriptions, along with biological profiles, have facilitated several potential identifications and DNA results are currently pending. Resources for decedent identification within the United States, such as NamUs and CODIS often lack missing persons information or appropriate DNA family reference samples for comparison to UBCs. Therefore, the FACTS faculty and students also work with human rights groups such as the Equipo Argentino de Antropología Forense, the Colibrí Center for Human Rights, and foreign consulates, providing each agency with case information and skeletal analyses.

The Scientific Working Group in Forensic Anthropology (SWGANTH) suggest best practices in education and training in forensic anthropology should include theory, methods, techniques, and forensic casework. This large-scale effort to identify the UBCs in South Texas provides both mentorship and specialized forensic casework training opportunities for graduate and undergraduate students. Students are involved in every aspect of working toward the identification of the UBCs including: intake, maceration, washing clothes, entering personal effects and case information into databases, and collection of DNA samples. Student involvement in case analysis is reserved for graduate students and supervised by faculty. As recommended by SWGANTh, graduate students log their hours spent working on casework to track their specialized training. Student involvement in UBC identification efforts allows students to be involved in the holistic and collaborative nature of forensic anthropology and, in this case, provides exposure to a humanitarian crisis within the United States.

Undocumented Border Crossers, Human Rights, Identification

A69 **Surveying a Titan: An Argument for the Presence of Human Remains on the Wreck of the R.M.S. *Titanic***

Lucas N. Rolleri*, *Western Carolina University, Dept of Sociology & Anthropology, 101 McKee Bldg, Cullowhee, NC 28723*; and Cheryl A. Johnston, PhD, *Western Carolina Human ID Lab, Dept of Anthropology & Sociology, WCU, 101 McKee Bldg, Cullowhee, NC 28723*

After attending this presentation, attendees will have a better understanding of the events surrounding the sinking of the passenger liner R.M.S. *Titanic* along with possible unexplored locations within the wreck that may harbor human remains.

This presentation will impact the forensic science community by increasing awareness of the necessity of including individuals trained in the identification and recovery of human remains when surveying shipwrecks and the importance of eyewitness accounts when reconstructing historical events.

The first highly publicized maritime disaster to result in a significant loss of human life occurred in the early morning hours of April 15, 1912. After colliding with an iceberg the night prior, the White Star liner, R.M.S. *Titanic*, sank in the icy north Atlantic, taking 1,523 of her passengers and crew with her. For the next 73 years, the wreck of the 882-foot-long ship lay undisturbed nearly 2.5 miles below the ocean surface. In 1985, the sunken ship was discovered and, in the ensuing years, multiple salvage expeditions have descended to the site. To date, no human remains have been recovered from the debris field that encircles *Titanic's* fragmented hull.

In the years since she sank, *Titanic* has ceased to be merely a ship, instead approaching enigmatic status and her wreck remains one of the most visited wrecks in the world. However, no expeditions have journeyed deep enough into the liner's hull to definitively rule out the presence of human remains. Historical records and eyewitness accounts indicate that at least one area of the ship has the potential to reveal the remains of crew members trapped by the rising waters.

This area is the forward mail holds, located on G-deck. R.M.S. *Titanic*, as a Royal Mail Steamer, was in service to the British government to bring mail to and from America. This task was charged to five postal clerks, each of whom were contracted by the White Star Line. Minutes after her fatal collision with the iceberg, *Titanic* was fast taking on water and among the first to notice this were the mail clerks. Their desperate attempts to save the mail were in vain. As the vessel's bow sank deeper into the Atlantic, the mail clerks ran back and forth between the holds on G-deck and the empty state rooms on D-deck, trying to outpace the rising water. All five men perished in this endeavor.

In April 2015, *Titanic* will have lain on the ocean floor for 103 years. The standard argument against the presence of human remains on the wreck is that this length of time is sufficient to have allowed bacteria and deep-sea scavengers to remove all traces of organic matter. This line of thought fails to take into account the presence of organic matter in recessed areas of the hull that have escaped destruction. Remains of the victims of maritime disasters that occurred within a similar timeframe to *Titanic* have also been recorded.

The most well known of these analogous disasters was the 1914 sinking of the R.M.S. *Empress of Ireland*. After a collision with another vessel, the *Empress* sank with the loss of 1,012 lives. Resting in waters easily accessible by experienced divers, the liner has become well known for the skeletal remains of her victims that linger on the wreck.

The other flaw with the current party line about remains on the wreck of *Titanic* is that the principle players making this judgment are not experts in human anatomy. Robert Ballard, a noted oceanographer, and James Cameron, the Hollywood director, are titans in their respective fields and have well-deserved reputations as experts in those fields; however, neither has the training necessary to identify human skeletal remains, particularly fragmented remains.

It is entirely possible that no trace of human remains persist on the wreck of the former White Star Line flagship; however, it is argued that the presence of remains cannot be ruled out. By looking at the historical documentation of the last known locations of individuals during the sinking, notably the postal clerk staff, an argument is made that further exploration inside the wreck is warranted before a statement on the presence or lack of human remains can be made.

***Titanic*, Ocean, Historical**

Anthropology Section - 2015

A70 Utilizing Geographic Information Systems (GIS) to Analyze Geographic and Demographic Patterns Related to Forensic Case Recovery Locations in Florida

Katharine E. Kolpan, MA, University of Florida, Dept of Anth, Turlington Hall, PO Box 117305, Gainesville, FL 32611*

After attending this presentation, attendees will have a better understanding of how GIS can be utilized by forensic anthropologists and the forensic science community at large and how GIS has elucidated patterns of body recovery at the C.A. Pound Human Identification Laboratory (CAPHIL) at the University of Florida.

This presentation will impact the forensic science community by demonstrating how the application of GIS provides a powerful tool for understanding the spatial distribution of case recoveries within specific geographic and cultural areas.

GIS can be used to provide information about the physical and cultural environment that humans inhabit. As such, it is a valuable tool that can be utilized to provide information about overall patterns of body recovery. In the case of this research, this study examines how geographic and demographic factors, such as topography, population density, and crime rates influenced or affected the spatial distribution of the forensic anthropology cases that are analyzed by the forensic analysts at CAPHIL.

In order to look for patterning, 92 cases spanning a five-year period (2007-2012) were selected and geolocated to a map of Florida using the program ArcGIS®. Recovery sites were selected for geolocation based on the following criteria: they contained human remains, they were recovered in the state of Florida, and the data on their recovery location was sufficiently complete for geolocation. Private cases and scene searches that did not yield human remains were excluded. ArcGIS® is equipped with a feature that allows the user to input addresses from a database file and use those addresses to create a point feature class data layer. Thus, each geolocated CAPHIL case appeared as a specific point in an ArcGIS® data layer that could interact with existing data layers collected from the Florida Geographic Data Library (FGDL), which serves as a repository for GIS map data created by state and federal institutions, such as the Florida Fish and Wildlife Conservation Commission and the United States Census Bureau.

The results of overlaying geolocated cases over map layers of physical land cover (swamp, forest, agricultural land, etc.), population density, and crime rate indicate that for the five-year period examined, the majority of cases brought to the University of Florida were recovered from designated urban areas, were found in areas of low population density (less than 300 people per square kilometer), and that the majority of remains were recovered from areas with very low to medium crime rates (a Police Report Index of less than 25,000 reports filed annually; less than 30 murders annually). Seventy-seven percent of geolocated cases were recovered from urban areas. Interestingly, though land cover maps designate these areas as environmentally urban, this does not make them synonymous with densely populated areas due to the fact that 48% of case recoveries were from areas of low population density. Regarding the relationship between crime rate and the selected cases, this study found that 78% of cases were recovered from areas with less than 25,000 police reports filed annually and 75% of cases were found in areas designated medium to low in terms of annual murder rates. Chi-square statistical analysis revealed all results to be significant.

While the results of this study convey important information about the spatial patterning of case recoveries in Florida and indicate how GIS can be employed to aid the forensic anthropology community at large, the lack of proper addresses and/or GPS coordinates from individuals recovered from a few very remote locations, such as the Ocala Nation Forest and open water areas off the Florida Keys, contributes to a certain amount of underenumeration. In many of these cases, issues regarding underenumeration of certain physical environments could be solved by encouraging the individuals conducting the recovery of the remains to take a GPS coordinate of the recovery location when possible. Though underenumeration does occur and not all cases will possess the requisite information for inclusion, GIS remains a powerful tool in regard to understanding potential patterns related to the spatial distribution of case recoveries.

GIS, Case Recoveries, Florida

A71 **The Application of the Sub-Pubic Concavity/Contour for Sexing Subadult Human Innominates**

*Alexandra R. Klales, PhD**, Mercyhurst University, Dept of Applied Forensic Sciences, 501 E 38th Street, Erie, PA 16546; and *Tesa L. Burns**, 263 Riverview Terrace, Dauphin, PA 17018

After attending this presentation, attendees will understand the timing and onset of sexual dimorphism in the morphology of the pubis which is commonly used for non-metric sex estimation of human remains.

This presentation will impact the forensic science community by testing the applicability, reliability, and validity of a trait commonly used in adult sex estimation for the prediction of sex in unknown subadult individuals encountered in forensic cases. The revised method presented in this research can be used to estimate sex in individuals younger than previously reported in the literature.

Sex estimation is essential for the assessment of a biological profile in forensic cases. While the innominate is considered the best indicator of sex in adults and is widely used for sex estimation in forensic cases, the use of the innominates for subadult sex estimation has been limited. Numerous studies have assessed the utility of other areas of the innominate (ilium/ischium), yet few studies have attempted to address the usefulness of the pubic bone for subadult sex estimation. A preliminary study on subadult pubic bones from the Hamann-Todd Osteological Collection has shown that it is possible to use a modified version of the Klales et al. method to estimate sex in subadult age categories younger than previously believed.¹ The results from this preliminary study were encouraging; however, a larger sample size was needed for the results to be statistically significant. The present research examines the subadult pubis using a revision of the Klales et al. Sub-Pubic Contour (SPC) scoring in a large sample of subadults.¹ The first goal of the study was to determine if this revised technique can be used to differentiate sexes in subadult remains. The second goal was to evaluate the timing or onset of sexual dimorphism in the SPC. The third goal of the study was to test the level of observer agreement for trait scoring.

The sample used in this research was derived from the PATRICIA Radiographic Data Bank. The database contains radiographs from a “geographically and ethnically diverse” sample of modern American subadults (born after 1990) with known demographic information collected from various coroner and medical examiner offices throughout the United States.² A total of 334 individuals of both sexes (149 females, 185 males) were included in this research. Individuals in the sample ranged in age from 1.19 to 20.47 years. The sample was divided into six age cohorts that were slightly modified versions of the age categories presented in Baker and colleagues: (1) Young Child Early (1.0 to 3.5 years); (2) Young Child Late (3.6 to 6.5 years); (3) Older Child Early (6.6 to 9.5 years); (4) Older Child Late (9.6 to 12.5 years); (5) Adolescent Early (12.6 to 15.5 years); and, (6) Adolescent Late (15.6 to 20.5 years).³ Two observers, one experienced and one upper-level anthropology student, scored each radiograph using a revision of the Klales et al. adult SPC scale/figures.¹ For the present research, the original adult SPC scores were reduced from five ordinal scores to three. First, trait frequency distributions for each ordinal score by sex were calculated for each of the age cohorts. Next, sex classification accuracy using SPC ordinal scores was tested using Ordinal Logistic Regression (OLR). Lastly, the Intraclass Correlation Coefficient (ICC) was utilized to test the degree of agreement for trait scoring between the experienced and inexperienced observer.

Score frequencies varied by age cohort. Score frequencies shifted away from Score 2 (straight), which was most common in the younger age cohorts, to a higher frequency of Score 3 (convexity) in males and a higher frequency of Score 1 (concavity) in females with increasing age. Using OLR, sex classification accuracy was highest for the oldest age cohort (Adolescent Late) at 97.2% combined correction classification and then decreased in order of age. Using the ICC, inter-observer error between the two scores rendered a high level of agreement (0.806) and mirrored the results of the original Klales and colleagues study. Results from this research indicate that the SPC method used in adult sex estimation can be modified and applied to subadult remains to accurately estimate sex of unknown subadults following the onset of puberty (around 12 years of age) with a high degree of reliability and validity.

Biological Profile, Subadult Sex Estimation, Pelvis

A72 Sex Estimation of the Modern Human Pubic Bone Using a 3D Geometric Morphometric Approach

Valda Black, MA, 1134 NE Markley Drive, Apt 3, Pullman, WA 99163*

After attending this presentation, attendees will have gained a greater understanding of the morphological differences seen between male and female modern pubic bones and how those shape differences can be captured using a 3D geometric morphometric approach.

This presentation will impact the forensic science community by quantifying non-metric shape analyses that are widely used in sexing human pubic bones through a 3D geometric morphometric approach for analysis. Using a 3D geometric morphometric approach allows for the utilization of landmarks and semi-landmarks to accurately capture the slight shape differences that non-metric observations are unable to obtain.

Sex estimation methods for human skeletal remains have been a highly researched and debated topic in biological anthropology. A plethora of studies have been performed using various statistical methods, in part because os coxae variation spans a large spectrum and does not always fit into distinct nonmetric categories. Growing in popularity is the utilization of 3D geometric morphometric techniques; studies have been performed using landmarks and semi-landmarks to sex os coxae with a high degree of accuracy.

Generally, it is believed that male pubic bones tend to be shorter and triangular in shape, while females have a longer and squarer shape. Previous studies acknowledge the need to quantify non-metric methods while sexing os coxae, but do not specifically test the widely used non-metric visual method of sexing males on the basis of short or triangular pubic bones and females on the basis of long or square pubic bones.

In this research, 35 known male and 35 known female specimens from the William M. Bass Donated Skeletal Collection at the University of Tennessee (UT) and 24 unknown specimens from the Forensic Anthropology Unit at the New York City Office of Chief Medical Examiner (NYC OCME) were scanned using a NextEngine® 3D laser scanner. The os coxae were edited in Geomagic® and eight landmarks were placed on the left pubic bone. The landmarks were chosen to highlight the portion of the pubic bone associated with the triangular and rectangular shape differences between males and females. These points were placed on the dorsal aspect of the bone since there are fewer irregularities and span from the superior and inferior portions of the pubic symphysis, along the obturator foramen opposite the symphysis points, and up to the most superior point of the obturator foramen. The points were aligned using a Generalized Procrustes Analysis, and then a Principal Components (PC) analysis was employed to distinguish meaningful shape differences. A Discriminant Function Analysis (DFA) was then run on the PC scores to determine how accurate the captured portion of the pubic bone is in determining sex. The known specimens were placed in their proper sex categories for the DFA analysis, while the unknown specimens were left ungrouped to compare the non-metric analyses of those os coxae found in their case reports versus their assigned group in the DFA analysis.

Using the 12 PC scores that contained significant shape information, the DFA analysis was able to classify 95.7% (94% males, 97% females) of the known UT pubic bones correctly into their skeletal sex groups with a 92.9% (91% males, 94% females) leave-one-out cross-validation accuracy. For the unknown NYC OCME specimens, 83.3% of the specimens matched their case reports. Intra-observer error was tested by placing the landmarks on the specimens a second time and running the same analyses. The results were an original classification accuracy of 97.1% (94% males, 100% females), a cross-validation accuracy of 91.4% (86% males, 97% females), with 87.5% of the unknown specimens matching their case reports. The differences in percentages between these two analyses are slight and the changes were due to specimens that fell within the overlapping regions found on the PC plots.

The results capture the major morphological differences between male and female pubic bones. These differences match the non-metric categories of a triangular shape in males and a square shape in females, which were found on the first PC, but it also captures 11 other significant PC variations that cannot be observed from visual assessments. This experiment has high accuracy results and can be a good categorization method for unknown specimens in future studies.

Geometric Morphometrics, Sex Estimation, Discriminant Function Analysis

A73 Estimating Sex From the Innominate Utilizing New Measurements

Sarah Baumgarten, BA*, 746 E 29th Street, 2nd Fl, Erie, PA 16504; and Stephen D. Ousley, PhD, Dept of Applied Forensic Sciences, Dept of Anthropology, 501 E 38th Street, Erie, PA 16546

After attending this presentation, attendees will understand how the use of newly devised measurements, including maximum and minimum measurements of the innominate for sex estimation, can provide extremely high accuracy rates and reduce errors associated with differential interpretations of landmark locations in traditional measurements.

This presentation will impact the forensic science community by introducing novel measurements that circumvent errors introduced by differential interpretations of traditional landmark-based measurements, resulting in an improved rate of accuracy of sex estimation in human identification, along with reduction of intra-observer errors.

The innominate is commonly viewed as the best skeletal element used in the estimation of sex of an unknown individual and non-metric methods have dominated. However, metric methods can provide a more objective means of estimation. Previous metric studies cite accuracy rates in at least the 90% range, though many of these methods use measurements based on landmarks that are difficult to find and nearly impossible to replicate, leading to high inter-observer error rates. Most recently, Murail et al. defined a series of measurements through text and images and analyzed them using logistic discriminant analysis, in a computer program known as Diagnose Sexuelle Probabiliste (DSP).¹ Their study showed accuracy rates of at least 95% in diverse samples from around the world, apparently avoiding bias in sex classification due to ancestry. Though this study seems to provide highly accurate results, their DSP program does not provide the actual logistic regressions used, a necessity in the post-*Daubert* era.

In this study, measurements with clear landmarks or those involving a maximum or minimum were used as is or were modified from previously published definitions, some of which were rather unclear. A sample of 100 male and 100 female innominates from Whites and Blacks in the Hamann-Todd Collection were used for this study. The individuals used were of known age, ranging from 19 to 96 years old, with known sex and ancestry. Only innominates from the left side were used for consistency. On each innominate, 11 measurements were taken with a digital sliding caliper connected directly to a computer to record the measurements efficiently and reduce data input errors. The data were analyzed using FORDISC® 3.1 discriminant function analysis, using both stepwise and non-stepwise functions. All reported error rates were cross-validated.

Using stepwise discriminant function analysis, a combination of five variables were shown to provide classification accuracies of 96% in males and 99% in females, for a pooled-sex accuracy of 97.5%. The five measurements selected by the stepwise discriminant function analysis included minimum apex to symphysis, maximum innominate length, maximum ischial length, maximum innominate breadth, and maximum pubic length. These measurements are effectively able to capture dimorphism in the innominate, with the measurement of minimum apex to symphysis, which captures true pelvic morphology; maximum innominate length and maximum innominate breadth, which capture information on the ratio of height to width; and maximal ischial length and maximum pubic length, which capture the ratio of pubis to ischium. Some logistic regression and other classification methods produced similar or higher classification accuracies with little sign of classification bias for sex by ancestry. Forty individuals were measured a second time to calculate the technical error of measurement and coefficient of reliability for each measurement. The technical error of measurement showed differences between rounds of measurements to be less than 2mm, a mean of less than 3.5% for all measurements, signifying low intra-observer error rates. Additionally, for all but two of the measurements, the coefficient of reliability values were greater than or equal to 0.96, indicating an extremely high level of intra-observer consistency for those measurements.

The high levels of intra-observer agreement between rounds of measurements reveal the value of measurements with clear, unambiguous landmarks, or those that involve maxima and minima. This approach proves that current methods can be further improved upon to reduce measurement errors and increase classification accuracy.

Sex Estimation, Forensic Anthropology, Innominate

A74 Sex Estimation Using Metric Measurements of the Sternum

Megan Chapin, BA*, 254 Lovell Place, Erie, PA 16503-2622

After attending this presentation, attendees will understand the benefit of including sternal measurements in traditional postcranial metric analyses. By understanding how the sternum can be utilized for sex estimation, an appreciation of how all bones contribute to constructing a biological profile will be gained.

This presentation will impact the forensic science community by presenting testable metric measurements of the sternum that display a high degree of differentiation between the sexes.

Though the innominate is most commonly used for skeletal sex estimation, post-cranial measurements have also proven to be accurate and useful due to the fragile nature of the pubis. Due to the incomplete or fragmentary nature of forensic cases, the need to use any available bones to produce a more accurate biological assessment of the individual cannot be overstated. Work by Jit et al. using Indian sternums produced a 84.9% classification accuracy for males and 88.6% accuracy in females.¹ Dahiphale's 2002 validation study of Jit et al. further demonstrated the feasibility of this method with classification accuracies of 92% for males and 87% for females.²

This study used metric measurements on sterna from an American group of Blacks and Whites from the Hamann-Todd Collection for use in sex estimation. A total of 152 individuals were used, with 76 males and females, respectively. Six measurements were taken to the nearest millimeter from the manubrium and sternal body using digital sliding calipers. Data was then analyzed using the statistical program R and FORDISC®.^{3,4} All accuracy rates were evaluated using discriminant function leave-one-out cross-validation. Measurements were analyzed individually, together, and using forward stepwise selection to classify an individual based on the best measurements available. All functions were tested for within-group variance-covariance matrix homogeneity, a requirement for linear functions, using the Kullback test. A forward mean stepwise analysis was also run to produce a cross-validated classification for ancestry, as well as for ancestry and sex combined.

The Kullback test *p*-value was greater than 0.01 for all analysis, meaning the hypothesis that the variation in each group is more or less the same was accepted. Each measurement alone classifies individuals by sex at a rate higher than 80% with the exception of breadth of the third sternal body and breadth of the last costal notch. The best function for sex classification was the four variable forward mean stepwise selection function (Breadth of First Costal Notch (-0.383))+Height of the Sternal Body (-0.174)+Maximum Manubrium Height(-0.161)+Breadth of the Manubrium(-0.048)+38 which showed a 91% sex classification accuracy. When the value is greater than zero, the individual is classified as female; if less than zero, the individual is classified as male.

Discriminant function analysis for ancestry using forward mean stepwise chose three measurements with an accuracy rate of 50.9% for females, not better than random; however, the ancestry samples used in this study had different proportions of males and females in each ancestry group. Discriminant function analysis for males needed only two variables in the forward mean stepwise function to produce a classification rate of 64.9%. When the classification of groups by sex and ancestry was run using stepwise, 58.5% of the total sample were classified correctly, suggesting that the sternum shows no metric differences based on ancestry.

This study proves the utility associated with sternum measurements in American groups. By displaying the effective classification by sex, it is the hope that future steps can be made to include the sternum in postcranial measurements.

Sternum, Sex Estimation, Postcranial Measurement

A75 Skeletal Sex Assessment Utilizing the Fifth Lumbar Vertebra

Sean Y. Carlson-Greer, BA*, 1414 Westminister Street, Saint Paul, MN 55130

The goal of this presentation is to explore the levels of sexual dimorphism found in the fifth lumbar vertebra and to specifically examine the utility of 11 linear measurements taken from an American sample of vertebra for sex assessment.

This presentation will impact the forensic science community by increasing the range of skeletal elements that can be utilized for determining the metrics for sex estimation and by beginning to explore the potential differences in levels of sexual dimorphism between vertebra and populations.

Sex estimation is a vital part of any investigation of unidentified human remains as it narrows the pool of potential victims. While well-accepted methods of sex estimation for the cranium and many postcranial elements exist, levels of sexual dimorphism have not been established in all skeletal elements; however, this is becoming vitally important in cases where remains may be fragmentary or incomplete and many heavily relied-upon methods may fail.

Over the last two decades, research has been pursued in exploring sexual dimorphism in select vertebra from a variety of populations.¹⁻³ These studies have resulted in varying levels of success, with overall sex estimation accuracies of approximately 85%. Of the three previously cited studies, two examined vertebra below the level of the sixth thoracic, both using data collected from Computed Tomography (CT) scans on East Asian populations.^{2,3} Though their results show promise, the applicability of these methods to measurements taken on dry bone from external populations needs validation.

The present study examined 11 linear measurements from 160 fifth lumbar vertebra housed in the Hamann-Todd Collection at the Cleveland Museum of Natural History in Cleveland, OH. Of the 160 individuals, 41 are documented as White males, 39 as White females, 39 as Black males, and 41 as Black females. Individuals in the sample were between the ages of 16 and 93 years old. The measurements include maximum dimensions of the vertebral body, pedicle widths, maximum widths of articular processes, transverse processes, and length of the spinous process. Statistical methods including discriminant function analysis and principal components analysis were run on the collected measurements to examine the level of sexual dimorphism in the sample.

Of the measured vertebral dimensions, anterior posterior dimensions of the vertebral body are the most dimorphic from this sample. Classification accuracies were found to be 78% and 77% for American Blacks and American Whites, respectively. Cross-validated sex estimation accuracies using discriminant functions increased this accuracy by only one to two percentage points when ancestries were pooled. These results are much lower than those reported in studies using Korean and Chinese CT populations. This could be for any number of reasons, all of which require further investigation. These include differences in measurement technique from 3D CT to dry bone, differences in population sexual dimorphism, and differences in vertebral level sexual dimorphism.

Anthropology, Vertebra, Sex Assessment

A76 Sexual Dimorphism of the Manubrium in a Modern Forensic Sample

Cristina L. Kelbaugh, BS*, 6001 Palm Place Lane, Apt 136, Tampa, FL 33647; Meredith L. Tise, PhD*, University of Lincoln, School of Life Sciences, Brayford Pool, Lincoln LN6 7TS, UNITED KINGDOM; John W. Powell III, BS, 123 SE 16th Avenue, Apt K203, Gainesville, FL 32601; Erin H. Kimmerle, PhD, University of South Florida, Dept of Anthropology, 4202 E Fowler, SOC 107, Tampa, FL 33820; and Leszek Chrostowski, MD, 11025 N 46th Street, Tampa, FL 33617

After attending this presentation, attendees will be familiar with metric sex estimation using the manubrium in a modern forensic sample in the United States. Previous studies have used measurements of both the manubrium and the mesosternum to develop sex estimation methods; however, these methods tend to focus on only the manubrium length in combination with the other standard sternal measurements. The objective of this research is to test a sex estimation method using measurements that encompass the overall shape and articular surfaces of the manubrium, rather than just the length, in order to define sectioning points for males and females using the manubrium without the mesosternum.

This presentation will impact the forensic science community by offering further research into sex estimation methods using postcranial skeletal elements. This is important in cases where only postcranial elements are found postmortem due to taphonomic damage or animal scavenging.

Forensic anthropologists estimate sex as part of the biological profile that is created to aid with human identification. For this research, a sample consisting of 303 known individuals (202 males and 101 females) from the Hillsborough County Medical Examiner's Office in Tampa, FL, was used. All individuals in the sample were between the ages of 20 to 86 years old; any cases with arthritic changes to bone, open-heart surgery, or other medical disturbances were excluded. Seven total measurements were collected on processed manubria removed at the time of autopsy. Using sliding calipers, the traditional manubrium length measurement was collected, in addition to six newly defined measurements: superior manubrium breadth, middle manubrium breadth, inferior manubrium breadth, height of right and left costal notch one, and thickness of manubrium body.

A Discriminant Function Analysis (DFA) was run in statistical analysis software to determine which measurement, or combination of measurements, was the most accurate when estimating sex, as well as if any of these results were as accurate as the results found in previously published studies that also incorporated the mesosternal measurements. The highest cross-validation classification rates resulted when using all seven manubrium variables with 90.91% for males and 81.82% for females (86.37% overall). When assessing the individual measurements separately, the inferior manubrium breadth had the highest cross-validation classification rates of 77.14% for males and 81.25% for females, followed by thickness of manubrium body with 76.66% for males and 71.74% for females. The overall cross-validation classification rate was only 68.4% when using only manubrium height (the standard manubrium measurement).

These results are similar to those found by Bongiovanni and Spradley with an overall cross-validation classification rate of 84.12% when using both the manubrium and sternal body measurements.¹ By incorporating additional measurements that were created to capture more of the manubrium shape and morphology of the articular surfaces, the cross-validation classification rates increased to be comparable to those found when using the manubrium and mesosternal measurements. The goal of this study was to explore sexual dimorphism of the manubrium as an applicable technique to use in forensic anthropological casework; the results suggest that the incorporation of the proposed measurements of the manubrium can be used to estimate sex, especially in combination with other sex estimation techniques.

Manubrium, Sex Estimation, Discriminant Function Analysis

Anthropology Section - 2015

A77 Feature Analysis of the Pubic Bone for Estimation of Age-at-Death

Julia D. Chmaj, BA*, 5010 Creekside Preserve Drive, Hixson, TN 37343; and Kristen Hartnett, PhD, OCME, Forensic Anthropology, 520 1st Avenue, New York, NY 10016

After attending this presentation, attendees will better understand which features of the pubic bone have the strongest correlation with age-at-death.

This presentation will impact the forensic science community by providing attendees with an in-depth evaluation of features from the most preferred region for age-at-death estimation. This information may assist the forensic anthropologist in producing a more accurate and reliable estimation of age-at-death.

During an individual's lifetime, the pubic symphysis will go through phases of epiphyseal formation, quiescence, and secondary changes related to age; it is these changes that are used in estimating age. The value of the pubic symphysis as an age indicator lies in the changes it continues to undergo when the rest of the skeleton has ceased to grow.

Assessment of a given morphological pattern and its age distribution is a difficult and challenging task when the individual features of the pubic symphysis express different age stages. In 1998, Suchey and Katz hoped that "studies of single traits will help produce narrower age ranges."¹ By observation and analysis of each feature individually, there may be a way to facilitate placement into the correct phase or age range.

The purpose of this research is to evaluate certain individual morphological features on the pubic bone to determine which are most strongly correlated with age-at-death. A known-age sample consisting of 156 female and 168 male pairs of pubic bones from the Forensic Science Center in Phoenix, AZ, was evaluated. Nine separate features of the pubic bone were scored on all specimens. Both left and right sides were examined and the oldest score was used. At the time of scoring, sex was known but age was not. The features scored were: (1) ridges and furrows (RID); (2) dorsal lipping (DOR); (3) bone quality (BONE); (4) rim formation (RIM); (5) the pubic tubercle (PUB); (6) depression of the symphyseal face (SYM); (7) ossific nodules (OSS); (8) ventral ligamentous outgrowths (VENT); and, (9) the ventral hiatus (HIAT). Features were scored according to a specific scoring system developed. Inter-observer and intra-observer error of the scoring system was assessed by four volunteers with different levels of experience from graduate students in physical anthropology to forensic anthropologists with PhDs.

Comparison of the results from the Pearson's correlation, Analysis of Variance (ANOVA), and simple regression analyses indicate that the nine features chosen for analysis are significantly correlated with age-at-death in the combined-sex sample. However, the Pearson's r values 0.762 (BONE), 0.731 (RIM), and 0.677 (VENT) and the F coefficients from the ANOVA 155.83 (BONE), 99.68 (RIM), and 90.13 (VENT) indicate that bone quality, rim formation, and ventral ligamentous outgrowths are more strongly associated with age-at-death than the other features. R -values for these specific features in the female sample were .819 (BONE), .790 (RIM), and .735 (VENT); r -values for the male sample were .701 (BONE), .696 (RIM), and .647 (VENT). The F coefficients for the female sample and the male sample were 110.09 (BONE), 68.17 (RIM), 59.68 (VENT) and 54.54 (BONE), 40.88 (RIM), 40.12 (VENT), respectively. The largest adjusted R^2 values for the total sample are from bone quality, rim formation, and ventral ligamentous outgrowths, respectively explaining 58%, 53%, and 46% of the variation over what would be expected by chance. The adjusted R^2 values of bone quality, rim formation, and ventral ligamentous outgrowths in the female sample are 67%, 62%, and 54% and 49, 48, and 42% in the male sample. These findings suggest that these three features are the best predictors of age-at-death in the total sample, as well as by sex.

Inter-observer error is low for most features, except dorsal lipping and ossific nodules, which were scored inconsistently across observers. Intra-observer test results indicate the majority of features are easy to evaluate, the exceptions being ossific nodules and dorsal lipping in the male sample.

The results of this study highlight bone quality, rim formation, and ventral ligamentous outgrowths as the features on the pubic bone that are most strongly correlated with age. In addition, the evaluation of bone quality of the overall pubic bone places the focus beyond the symphyseal surface and provides a means to assess older individuals previously thought impossible to age. Future studies should emphasize bone quality and analyze other collections in and out of the United States.

A78 Assessing the Effects of Pregnancy on Aging From the Pubic Symphysis: Incorporating Living People Into Biological Profile Research by Combining Medical Imaging and Participant Interviews

Janamarie Truesdell, MS, University of Oxford, Wolfson College, Linton Road, Oxford, Oxon OX2 6UD, UNITED KINGDOM*

After attending this presentation, attendees will gain an increased understanding of the effect of pregnancy on the face of the female os pubis and its impact on aging accuracy as well as a practical introduction to the value and implementation of living patients in biological profile research.

This presentation will impact the forensic science community by introducing a novel means of future data collection combining medical imaging technology and patient observation and interviews.

One of the major restricting factors in biological profile research continues to be the limited availability of data representing current populations. Each year, historical collections become further removed in diet, activity, environment, and general lifestyle from the people of today, prompting an increasing shift to skeletal material that has been generously donated, sanctioned for study after conflict, or collected during autopsy. By incorporating the medical imaging of living volunteers, this study sought to investigate an additional methodology for modern data collection that allowed for both unlimited sample size and the inclusion of life history information provided first-hand by the subjects themselves.

Anecdotal evidence has long associated pregnancy with the difficulty and disproportioned inaccuracy of aging from the face of the female os pubis. However, as previous studies have exclusively utilized physical postmortem specimens (mainly from autopsy), both lifestyle and birth history information has been basic and of debatable accuracy (as, by necessity, it was/is gathered from secondary and tertiary sources such as medical records and/or family and friends). Perhaps as a result, in the absence of a solution, publications moved away from examinations into pregnancy and parturition and into so-called “what” investigations such as methods comparisons, 3D surface mapping, advocating for a 7th phase, and the creation of new equations for narrowing age-at-death to smaller, more specific ranges. In setting living participants as its data set, this study sought to focus more on the “why” of symphyseal change than on the “what.”

By working within Britain’s National Healthcare System (NHS) and Oxford University Hospital’s system (OUH), for this study, access was obtained to any and all patients coming into radiology for scans involving the pubic symphysis (approximately 40-50 per day). Questionnaires detailing demographics and body type, diet, activity level, sports history, and smoking and alcohol consumption were then completed by both sexes, with an additional pregnancy history page given to females. All participants then signed consent for both their scan(s) and questionnaires to be included as part of this project. The scans were 3D volume rendered and a modification to the *Suchey-Brooks Method for Aging the Os Pubis* was applied by the both a person familiar with this study and three independent observers (blindly) to determine whether male, nulliparous females, and parous females could be distinguished from each other with any significant reliability. Additional patterns between life history and symphyseal change were also investigated.

While pregnancy and the pubic symphysis was chosen to illustrate this methodology, it is by no means the only application — utilizing the data of living subjects, coupled with participant observation and patient interviews, lends itself equally to more complex investigations such as the effect of substance abuse on over-aging or the effect of environment (both social and physical) on inter- and intra-population variation. Therefore, in addition to insights into the effects of pregnancy on the reliability of aging accuracy, attendees of this presentation will be walked through the process of setting up partnerships with local hospitals, gain a basic knowledge of the different imaging modalities and their current uses, and receive an introduction to volume rendering as well as some of the software currently available.

Pregnancy, Pubic Symphysis, Medical Imaging

A79 McKern's and Stewart's "Unknowns": A Reappraisal of the Individuals Omitted From the "Skeletal Age Changes in Young American Males" Sample

Alexander F. Christensen, PhD*, JPAC-CIL, 310 Worcester Avenue, Joint Base Pearl Harbor-Hickam, HI 96853

After attending this presentation, attendees will understand the nature of the reference sample for one of the foundational studies in forensic anthropology and how a reassessment of military records can improve this sample.

This presentation will impact the forensic science community by showing how one of the most important reference samples for studies of skeletal aging can be enlarged and improved.

McKern's and Stewart's *Skeletal Age Changes in Young American Males: Analysed from the Standpoint of Age Identification* is a foundational study in American forensic anthropology; however, since its publication, little attention has been paid to the original data for the study.¹ According to the monograph's introduction, data was collected from the skeletal remains of 450 American service members repatriated by Communist forces after the Korean War; however, only 375 of these individuals were ever identified. The Joint POW/MIA Accounting Command-Central Identification Laboratory (JPAC-CIL) is actively engaged in the exhumation and identification of unknown remains from the Korean War, and was therefore interested in obtaining additional data on these 75 service members.

McKern and Stewart did not directly analyze the skeletal materials for their project. Instead, Stewart collected data on 450 skeletal cases in the Central Identification Unit (Kokura, Japan), from September 1954 to January 1955. For each case, he scored a predetermined list of age indicators on two punch cards, wrote additional notes on the front of each card, took extensive photographs (a total of 3,861), and made a series of casts, generally including one pubic symphysis, one medial clavicle, and one lateral manubrium and/or corpus sterni. All materials were prepared in duplicate: two identical sets of punch cards were made, two 8"x10" images were printed from each negative, and two casts were made from each mold.

At the time of skeletal processing, the casualties were unidentified. As identities were determined, Stewart added notes to the cards that included dates of birth and death, home of record, cause of death, "national extraction" (determined from race combined with surname), and how the identification had been made (generally, the strength of the dental comparison with antemortem records, although occasional fingerprint comparisons are noted). Upon Stewart's return to the United States, the Army provided him with updates on casualties subsequently identified.

Stewart then sent one set of casts, photographs, and data cards to McKern so he could analyze them, while retaining the others at the National Museum of Natural History (NMNH). While he sent a complete set of casts, so that McKern could use all of them for seriation, he only provided the punch cards and photographs for the series of identified individuals, retaining both sets for the unidentified individuals. Stewart's set of casts are currently curated by the Department of Physical Anthropology while his data cards, notes, and drafts of his chapters of the monograph are in the National Anthropological Archives, both at the NMNH.

Recently the JPAC-CIL acquired the duplicate data cards collected by Stewart from 73 "unknown" individuals (it is not known what accounts for the discrepancy between the "known" totals of 375 reported in the monograph and 377 filed at the NMNH). Comparison of these cards with original military records revealed that, in fact, 37 had been identified as United States service members; it appears that these identifications were made after Stewart sorted out the cards. An additional nine were identified as Australian or British, and thus excluded from a study of "young American males." Two were determined to be Korean, and the remaining 25 were buried as Unknowns. Since 1999, JPAC has exhumed six of these 25 and identified four. These records thus provide an opportunity both to assess how well McKern's and Stewart's aging methods work on a known sample that was set aside from their analyses and to compare Stewart's casts, photographs, and data collection to the actual skeletal remains of some individuals. When their data cards and casts were used to generate age estimates for the 50 known individuals, the actual ages of 31 were within the estimated ranges. Six were younger (average of 1.55 years below the bottom limit of the estimate), while 13 were older (average of 1.67 years above the top limit of the estimate).

Finally, a longer-term project of collecting military records for the identified individuals will eventually provide additional biological information on the original 377 as well, including skeletal measurements and antemortem weights.

A80 A Reassessment of McKern's and Stewart's Pubic Symphysis Aging Method

Joan E. Baker, PhD*, DPMO, 2600 Defense Pentagon, Washington, DC 20301-2600; and Alexander F. Christensen, PhD, JPAC-CIL, 310 Worcester Avenue, Joint Base Pearl Harbor-Hickam, HI 96853

After attending this presentation, attendees will understand how inter-observer error affects age estimates using the McKern and Stewart pubic symphysis method and the impact of such error on forensic casework.

This presentation will impact the forensic science community by drawing attention to limitations of a particular skeletal aging method.

In their 1957 study, *Skeletal Age Changes in Young American Males: Analysed from the Standpoint of Age Identification*, Thomas W. McKern and T. Dale Stewart presented a new “component system” of assessing age from the male pubic symphysis using a reference sample of plaster casts made from the symphyses of 349 American casualties from the Korean War.¹ In 1983, Katz and Suchey published a revised method of symphyseal age determination, a modification of Todd's system that condensed ten phases into six.² Subsequently, this six-phase method has become the standard in American forensic anthropology; however, in the Joint POW/MIA Accounting Command-Central Identification Laboratory (JPAC-CIL), the McKern and Stewart method is used when analyzing the remains of World War II and Korean War casualties, because they are drawn from the same population as McKern's and Stewart's reference sample. This reassessment of McKern's and Stewart's method looks at two questions: (1) how difficult is the method to apply properly; and, (2) how accurate is it when applied to samples drawn from the same population as the reference series?

For the first question, two data sets were assessed. The first is a table of phase scores made available by Lyle Konigsberg, which he and colleagues collected in 1999 from the Korean War symphyseal casts, using both McKern's and Stewart's and Todd's methods.³ Notably, Konigsberg et al. scored the same series of casts that McKern had scored to develop his method. The second is a series of 66 Korean War casualties identified since 2000 for whom full component scores were available.

McKern's discussion of the component system highlights the relationship between the three scores: I≤II≤III. He only recorded 21 combinations within the reference series (vs. 216 possible combinations), which he explained by this chronological relationship. Logically, Konigsberg et al. should have obtained the same combinations; if they did not, this indicates some degree of inter-observer error. However, they observed 21 combinations that violate the general chronological progression, indicating that they applied the method differently. This study rescored 162 of these casts and obtained the same total score on only 45. On 61 casts, this study scored two of the three components the same, and on 40 only scored one the same. On 33 casts, the casts were scored as further advanced than Konigsberg et al. (mean difference of 1.45), while on 84 the casts were scored as less advanced (mean difference of 2.06).

The CIL data set consisted of skeletal individuals who were not in the original reference sample, but were drawn from the same population. A similar pattern was evident: CIL analysts observed 15 of McKern's 21 patterns, as well as 13 not seen by McKern. In both series, scores of 0 appear less frequently than expected, particularly on the second and third components; this is probably due to the absence of reference casts for these values.

For the second question, the symphyseal casts of 50 individuals who were omitted from McKern and Stewart's sample but for whom ages are now available were scored and assigned age ranges to each based on summary component scores. Of the 50, the actual age of 31 individuals fell within the range identified by McKern and Stewart. Thirteen were older than predicted, with a mean difference of 1.67 years between the predicted maximum age and the actual age. Six were younger than predicted, with a mean difference of 1.55 years between the predicted minimum and the actual age.

These results indicate that the McKern and Stewart method is indeed difficult to use accurately, even for experienced physical anthropologists. Furthermore, while the age estimates that it produces are smaller than those of Suchey-Brooks, which is appealing in forensic cases, they may falsely exclude the actual age, particularly if the method is not accurately applied.

Age Determination, Pubic Symphysis, War Dead

A81 Estimating Stature When Ancestry is Unknown: What Statistical Methods Work Best?

Ani N. Hatza, MS, Center for Forensic Science Research & Education, 2300 Stratford Avenue, Willow Grove, PA 19090; Stephen D. Ousley, PhD, Dept of Applied Forensic Sciences, Dept of Anthropology, 501 E 38th Street, Erie, PA 16546; and Luis L. Cabo, MS, Dept of Applied Forensic Sciences, 501 E 38th Street, Erie, PA 16546*

After attending this presentation, attendees will gain an in-depth understanding of key sampling and hypothesis testing issues that arise when estimating new equations to assess stature from skeletal elements. In particular, it will demonstrate the convenience of incorporating outgroup comparisons in the development of stature equations, including the appropriate hypothesis tests to assess whether the regression lines differ significantly from those for other samples or groups. This strategy serves to prevent overfitting to the reference sample, which is not addressed by goodness-of-fit measurements such as correct classification percentages or error rates.

This presentation will impact the forensic science community by demonstrating that, contrary to traditional assumptions, pooled-ancestry stature equations can be more appropriate than population-specific equations obtained from a single sample.¹⁻³ This implies that in many instances stature can be accurately and precisely estimated from the femur and tibia even when the decedent's ancestry is unknown.

The study examines this hypothesis and proposes new methods and criteria to assess whether it is necessary to subdivide samples from the same or different populations to create new, specific stature equations. Equations for five modern adult skeletal samples separated by different levels of genetic distance are compared using Analyses of Covariance (ANCOVA) to test whether regression lines actually differ across groups.^{4,5} In the absence of such differences, a single, common regression line is appropriate to estimate stature for those groups. ANCOVA also provides weighted estimates for the slope and intercept, accounting for the slopes and range of variables in all sample groups. This method provides a criterion to decide if separate equations should be calculated for new "populations" and compares the regressions obtained from several samples to address the issue of sample bias.

Results demonstrate that despite differences in mean height, the relationship between female stature and lower limb bone length is constant across several populations, indicating that specific stature equations are not always required for each ancestral group. More precisely, in the present example, the ANCOVA approach serves to reduce the total number of female equations from twelve to five, since no significant differences were observed between several of the groups. The observed differences across male groups were slightly greater than those of their female counterparts, but the total number of equations for male groups could still be reduced significantly.

By presuming that populations are significantly different, forensic anthropologists sometimes create a false need to calculate new stature equations.⁶⁻⁸ The results of this study indicate that it is more beneficial to first compare different sample populations using ANCOVA to determine whether or not the groups are truly significantly different, thus requiring new, population-specific stature regressions.

A82 The Issue of Age Estimation in a Modern Skeletal Population: Are Current Aging Methods Satisfactory for the Elderly?

Annalisa Cappella, BS, Via Mangiagalli 37, Milano 20133, ITALY; Marco Cummaudo, MA, LABANOF, V. Mangiagalli, 37, Milan 20133, ITALY; Elena Arrigoni, LABANOF, V. Mangiagalli, 37, Milan, ITALY; Daniele M. Gibelli, PhD, LABANOF, Sezione di Medicina Legale, Dipartimento di Scienze Biomediche, per la Salute, V. After attending this presentation, attendees will gain insight into the reliability of the current skeletal age-estimation methods tested on a modern cemetery population of known sex and age. The presentation will focus primarily on the issue of age estimation of elderly individuals for whom the identification of the correct age range seems more problematic. At the same time, an overview of the applicability of each method, based on the survival of the skeletal sites of application of the method, will be provided.

This presentation will impact the forensic science community by pointing out the advantages and the limitations of current methods of age estimation when approaching skeletal remains of elderly individuals.

The skeletal age estimation of individuals is one of the main tasks in forensic anthropology. From 1920 to the present, several methods have been developed, each with its limits, mean error, and age ranges in which that particular method proved to be more reliable. The main idea behind age assessment in adults is related to the analysis of the physiological degeneration of particular skeletal structures with age. The main issues with these procedures are due to the fact that they have not been tested on different populations and in different taphonomic contexts and that they tend to underestimate the age of older individuals. The methods currently used by anthropologists have in fact been standardized on archaeological and historical collections that may not completely reflect the characteristics of a modern population, especially from a demographic point of view. In addition, the increased life expectancy at birth has pointed out the need for further research on the estimation of age ranges in skeletal remains belonging to elderly individuals.

In the present study, the following methods were taken into account: Suchey-Brooks (symphysis pubis), Lovejoy (auricular surface of the ileum), Iscan (fourth rib's cartilaginous end), Meindl-Lovejoy (ectocranial sutures), Rougé-Maillart (acetabulum combined with auricular surface), and Beauthier (palatine sutures).

The purpose of this study was to test the applicability and the reliability of these methods on a contemporary population of skeletal remains of 165 elderly individuals of known sex and age (ranging between 50 and 98 years), exhumed 20 years after their burial. Although the skeletal remains were generally in good condition, some skeletal sites showed a lower survival due to taphonomic influences and consequently it was not always possible to test all the methods on the entire population. The results show that the methods with the highest percentage of applicability were Lovejoy (89%) and Rougé-Maillart (79%), followed by Suchey-Brooks (56%) and Meindl-Lovejoy (37%). Those with the lowest were Beauthier (36%) and Iscan (24%).

In regard to the age estimation accuracy, Rougé-Maillart (88%) and Lovejoy (82%) showed the best results in terms of the correct identification of the age ranges in which the chronological age of the individuals was included. These percentages are reduced to 70% with Suchey-Brooks (2σ), 64% with Beauthier, 46% with Meindl-Lovejoy, 45% with Iscan, and 20% with Suchey-Brooks (1σ).

Despite this, the only method that proved to be reliable when dealing with over-60-year-old individuals was Rougé-Maillart. The main limit of this method was due to the fact that the age ranges are too small (nine years). Therefore, at this time, the probability of associating an individual to the wrong age class is too high. The first step to improve the method could be the redefinition of the age classes in wider ranges without neglecting the need for further testing on a wider sample.

This research has shown how, for older adults, the study of both acetabulum and auricular surfaces may be more reliable for aging. This is also in accordance with the fact that auricular surface and the acetabulum are the areas that more frequently surviving taphonomic insult.

Forensic Anthropology, Age Estimation, Old Adults

Anthropology Section - 2015

A83 One Hundred Years Since Martin's Lehrbuch: Measurement Confusion and DCP 2.0

Stephen D. Ousley, PhD*, Dept of Applied Forensic Sciences, Dept of Anthropology, 501 E 38th Street, Erie, PA 16546; Natalie R. Shirley, PhD, Lincoln Memorial University, DeBusk College Osteopathic Med, 6965 Cumberland Gap Parkway, Harrogate, TN 37752; and Richard Jantz, PhD, University of Tennessee, Dept of Anthropology, Knoxville, TN 37996-0720

After attending this presentation, attendees will appreciate that there have been many versions of measurement definitions published and neither the primary nor secondary definitions are always ideal, due to poor descriptions, inaccurate or incomplete translations, or definitions for measurements that can at times be impossible to take correctly.

This presentation will impact the forensic science community by serving as a reminder that metric standards are necessary but have been corrupted through various means and a new approach to standards must be taken for consistency.

Measurement standards and definitions are difficult to write clearly, explicitly, and unambiguously, but are necessary in order to use metric methods of forensic analysis. At the beginning of the 20th century, there were a number of different cranial measurement standards of varying quality, largely in French and German. International standards for cranial and postcranial measurements were established in Monaco in 1906 and in Geneva in 1912. In 1914, Rudolf Martin published his *Lehrbuch der Anthropologie* and established measurement standards that have persisted in one form or another to the present. His definitions have remained unchanged in newer editions posthumously published and include comments on subsequent measurement definitions, such as those from Howells.^{1,2} The interpretations of Martin's definitions have dominated most anthropological metric standards since.

However, Martin's definitions have never been translated fully into English; they are at times extremely opaque, such as his definition for the landmark ectoconchion. In some cases, his definitions are somewhat contradictory, referring to the most inferior and most superior points initially, then specifying techniques to obtain a maximum measurement, such as in the maximum length of the femur. In 1973, W.W. Howells modified and clarified craniometric landmarks and measurements from Martin and others. One often-overlooked anthropologist, Aurel von Török was far ahead of his time. In 1890, his *Grundzuege einer Systematischen Kranimetrie (Essentials of a Systematic Craniometry)* defined more than 100 landmarks and listed more than 5,000 measurements on the cranium. He also advocated using a "universal craniometer" that would calculate all standard measurements, all interlandmark distances, and all possible angles, which modern digitizers and computers finally can do.

Most knowledge of Martin's definitions is indirect, from the *Standards* of Buikstra and Ubelaker (BUS) or University of Tennessee's (UT) *Data Collection Procedures (DCP1)*.^{3,4} BUS was supposedly based on translations of Martin in DCP1 and a few secondary sources; however, many of the definitions leave out specific information on techniques, meaning a "maximum" measurement may not be the actual maximum measurement. Some subsequent publications cite the definitions in BUS and find a maximum length of a femur that is smaller than the bicondylar length, which is impossible if the full Martin definition is used. Other information in BUS is simply incorrect, such as the locations of dacryon and ectoconchion: their figure 41 actually illustrates maxillofrontale and frontomolare anterior. These and other errors are propagated in other osteology references works, some of which cite BUS. The DCP1 is largely a translation of Martin with secondary sources cited, but the DCP1 procedure for maximum long bone lengths, taken by moving the bone up and down, left and right, apparently comes from Hrdlicka's *Anthropometry*, which was not cited.⁵ Hrdlicka was likely influenced, directly or indirectly, by studying anthropometric technique in France under Manouvrier in 1896, to whom his book was dedicated, but Manouvrier's definitions are not as explicit as Hrdlicka's. Whatever the source for Hrdlicka's standards, they seem to be consistent with his stated goal of providing "simple, practical, well-tested instructions." Finding maximum measurements in such a fashion should be more consistent among measurers than basing measurements on the most superior and inferior points.

Measurement standards must also evolve as technology and equipment changes. For more than 100 years, the standard instruments included sliding and spreading calipers. With the advent of 3D digitizers and scanners, and geometric morphometric methods, the Howell's measurement definitions which use landmarks defined independently of the measurement taken, are geometrically better than Martin's, whose landmark locations sometimes depend on the measurement being taken.

Anthropology Section - 2015

Examples from Martin to BUS to DCP1 remind the forensic science community that measurement definitions need to be clarified, improved, and, if necessary, changed, especially in light of the *Daubert* decision and the 2009 National Academy of Sciences Report, *Strengthening Forensic Science in the United States: A Path Forward*.⁶ Because definitions can always be improved and augmented, and the nature of publication has changed, versioning is necessary. Electronic standards can easily be versioned, and can include textual descriptions, methodological comments, illustrations, images, and even video instruction. All are necessary to establish consistent and reliable standards. These forms of information and instruction will be integral parts of *Data Collection Procedures for Forensic Skeletal Material 2.0*, which will provide “simple, practical, well-tested instructions” based on empirical data.

Craniometrics, Measurement Standards, Osteometry

Anthropology Section - 2015

A84 Evaluation and Reformation of Osteometric Data in Forensic Anthropology: The Foundations of DCP 2.0

Lee Meadows Jantz, PhD, University of Tennessee, Dept of Anthropology, 250 S Stadium Hall, Knoxville, TN 37996-0720; Natalie R. Shirley, PhD, Lincoln Memorial University, DeBusk College Osteopathic Med, 6965 Cumberland Gap Parkway, Harrogate, TN 37752; Shauna McNulty, MA, 250 S Stadium Hall, Knoxville, TN 37996; Heli M.K. Maijanen, MA, 250 S Stadium Hall, Knoxville, TN 37996; Stephen D. Ousley, PhD, Dept of Applied Forensic Sciences, Dept of Anthropology, 501 E 38th Street, Erie, PA 16546; and Richard Jantz, PhD, University of Tennessee, Dept of Anthropology, Knoxville, TN 37996-0720*

After attending this presentation, attendees will be aware of “problem” skeletal measurements and informed about error rates associated with measurements that interface with the FORDISC® program. This presentation will also introduce a new version of a popular laboratory manual: *Data Collection Procedures for Forensic Skeletal Material 2.0*.

This presentation will impact the forensic science community by addressing recommendations of the 2009 National Academy of Sciences (NAS) Report, *Strengthening Forensic Science in the United States: A Path Forward*. Specifically, the NAS Report stressed the need for “rigorous systematic research to validate the discipline’s basic premises and techniques.” This foundational research investigates the reliability, accuracy, and validity of forensic methods (Recommendation 3) and seeks to assist in the effort to establish valid and reliable methods and protocols that will serve as proficiency testing, training, and certification (Recommendation 6).

Many methods and techniques in forensic anthropology employ osteometric data as their basis, but little work has been done to investigate the error rates associated with these measurements. Metric data form the basis of the FORDISC® program used to develop a biological profile of unknown remains. Metric data also provide a straightforward means to quantify error; therefore, their use in forensic casework is increasingly common, particularly in light of the judicial atmosphere since *Daubert* (1993). Many components of a forensic anthropology case report are derived from osteometric data (i.e., sex, ancestry, stature). As such, error associated with any method that employs these data is compounded by the error that is inherent in the measurement(s), whether a function of the observer, the instrumentation, or both. Documented error rates will provide a foundation from which to proceed with metric estimations of the biological profile components, as well as method development.

Data collection was done on William M. Bass Donated Collection skeletons at the University of Tennessee. Four observers took 78 standard (34 cranial and 44 postcranial) and 20 less commonly used measurements on a sample of 50 skeletons using sliding calipers, spreading calipers, an osteometric board, and a mandibulometer; one observer repeated the measurements on the 50 skeletons three times with a two-month time lapse between sessions. Instruments were calibrated daily with a calibration rod. Absolute and relative Technical Error of Measurement (TEM), Scaled Error Index (SEI), percent error, and one-way and repeated measures Analysis of Variances (ANOVAs) were used to assess the degree of inter-observer and intra-observer error for each measurement.

Results indicate that maximum lengths and breadths have the lowest inter- and intra-observer values across the board (SEI values <2.0, relative TEM values <4.0, percent error <2%, and non-significant ANOVAs at $\alpha=.05$). The ten most reliable measurements are maximum femur length, bicondylar femur length, maximum humerus length, maximum fibula length, bizygomatic breadth, maximum ulna length, maximum clavicle length, maximum radius length, biauricular breadth, and scapula height. The 12 most unreliable measurements are ischium length, mastoid height, breadth of mandibular body, pubis length, interorbital breadth, vertical diameter of clavicle, proximal epiphyseal breadth of tibia, sagittal diameter of clavicle, transverse diameter of first sacral segment, transverse subtrochanteric diameter of femur, anterior sacral breadth, and A-P subtrochanteric diameter of femur (SEI values >2.0, relative TEM values >4.0, percent error >2%, and significant ANOVAs at $\alpha=.05$). Alternative maximum/minimum midshaft diameters were assessed as options to positionally dependent measurements such as sagittal and vertical clavicle diameters, dorso-volar and transverse ulna diameters, diameters at the nutrient foramen of the tibia, and sagittal and transverse radius diameters. The alternatives for the clavicle and ulna were found to be considerably more reliable than their aforementioned counterparts.

These results support an earlier report on inter-observer error of 22 postcranial measurements (Adams and Byrd) and have implications for forensic anthropology practice and research.¹ At the extreme, this study suggests that some measurements should be abandoned or replaced with more reliable alternatives if they are to be used in case analyses and method development. Others must be clearly explained and accurately translated in the available laboratory manuals. *Data Collection Procedures 2.0* will provide error rates for all measurements that interface with the FORDISC® software and include more reliable options for “problem measurements.” In addition, the new manual will clarify problematic definitions, include updated images, and interface with upcoming versions of the Forensic Data Bank and FORDISC® software.

Osteometric Data, Observer Error, FORDISC®

A85 Investigations Into Age-Related Changes in the Human Mandible

Nicolette Parr, PhD*, JPAC-CIL, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853; Nicholas V. Passalacqua, PhD, 1559 Mount Vernon, East Lansing, MI 48823; and Katherine Skorpinski, PhD, Joint POW/MIA Accounting Command, Central Identification Laboratory, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853

The goal of this presentation is to examine age-related osteometric changes in the adult mandible.

This presentation will impact the forensic science community by demonstrating that, despite previous claims, mandibular shape changes are more correlated with tooth loss than advancing age.

Recently, Shaw and colleagues argued that the adult mandible changes significantly with age. Using a sample of Computed Tomography (CT) scans from 60 males and 60 females, Shaw et al. examined six mandibular measurements and found that as both male and female individuals aged, there were significant decreases in ramus height, mandibular body height (equivalent to chin height using the Forensic Data Bank definitions established by Moore-Jansen et al. — the latter term will be used here for consistency), and the length of the mandibular body, whereas the mandibular angle increased significantly.^{1,2} However, Shaw et al. did not attempt to control for antemortem tooth loss, nor did they utilize the full set of standard mandibular measurements.

In order to more fully investigate the purported mandibular age-related changes, this study used a sample of 319 individuals from the W.M. Bass Donated Skeletal Collection (University of Tennessee (UT) Knoxville) and the Robert J. Terry Anatomical Skeletal Collection (Smithsonian National Museum of Natural History (NMNH)). A single observer collected the ten standard mandibular measurements and scored antemortem tooth loss according to the Eichner Index, which classifies tooth loss based on the presence of occlusal pairs. The sample consisted of 105 females with ages ranging from 17 to 99 years and 214 males with ages ranging from 16 to 84 years (total n=319).

A two-way Analysis of Variance (ANOVA) was used to determine if age, the Eichner Index, and the interaction between the two variables had an effect on the mandibular measurements. The current study found no significant difference between age and any of the standardized mandibular measurements ($p > 0.05$, in all instances); however, significant differences were noted between the Eichner Index and three mandibular measurements: chin height ($p < 0.001$), corpus height ($p < 0.001$), and the mandibular angle ($p = 0.031$). Additionally, no interaction was noted between age and the Eichner Index for any mandibular measurement.

The results indicate that no significant osteometric changes occurred in the mandible with increased senility, including ramus height, chin height, mandibular body length, and mandibular angle, as had been previously reported by Shaw and colleagues; however, significant differences between the Eichner Index and chin height, mandibular angle, and body height were found, suggesting that changes in the mandibular dimensions are more highly correlated with antemortem tooth loss than with age. It is widely known that socioeconomic gaps leave a large portion of the population without access to proper dental care; as such, antemortem tooth loss and subsequent mandibular shape changes may begin at an earlier age in these individuals. Alternately, such morphological changes may not occur or may be significantly delayed for those with better access to dental care. Given these findings, it may be necessary to re-evaluate previous notions of mandibular osteometrics and age, as these may be more a consequence of dental health than increased senility.

Mandible, Age Estimation, Osteometrics

A86 Accuracy of Estimating Age From Cervical Vertebrae and Mandibular Molar Maturation

Helen M. Liversidge, PhD, Queen Mary University of London, School of Dentistry, New Road, London E1 2AT, UNITED KINGDOM; and Scheila Manica, Queen Mary University of London, 7 Maiden Lane, London NW1 9YL, UNITED KINGDOM*

After attending this presentation, attendees will be able to: (1) recognize the potential of Cervical Vertebral Maturation (CVM) as a method of estimating age (particularly when third molars are mature or absent); (2) appreciate the difficulty in assessing biological age in juveniles in order to estimate chronological age; and, (3) understand the need for additional methods to estimate age in young adults between 16 and 21 years of age from radiographs.

This presentation will impact the forensic science community by emphasizing the importance of the fact that age estimation is required for identification of disaster victims and forensic cases as well as minors without documentation and age-disputed asylum seekers.

Shape changes during the maturation of cervical vertebrae are used to assess the pubertal growth spurt and are a potential method to estimate chronological age. The goal of this pilot study was to assess the accuracy of estimating age by CVM and mandibular second (M2) and third (M3) molars in a group of males. The sample consisted of lateral cephalograms of 60 boys aged 10 to 15 years from the Bolton-Brush online collection. A new method of cervical vertebral growth based on the changing size and shape of C2 to C6 was devised using raw data of 69 boys (aged 9 to 15 years) in Lamparski.¹ CVM ages were calculated by transition analysis. Dental age was calculated using molar ages from Liversidge.² The mean difference and absolute mean difference between CVM age and dental ages and chronological ages was calculated. CVM and molar tooth stage assessment reliability was assessed by duplicate readings from previous studies.

Results show that CVM age could only be calculated for 48 boys and those with a bone age of “10 years” could not be aged because of the minimum age of Lamparski’s sample. The number of individuals with M2 developing was 37 and with M3 developing was 43. Thirty-five boys had results for CVM, M2, and M3.

Results for accuracy of age estimation show that the mean difference using CVM was -1.10 years (SD 0.85, N=48), mean difference using for M2 was -0.86 (SD 0.69, N=38) and M3 was -0.37 (SD 0.98, N=43). Absolute mean using CVM was 1.21 year, M2 was 0.91 and for M3 was 0.83. These findings show that mandibular molars were more accurate in estimating age than this method of CVM. It is concluded here that there is a compelling need to develop an appropriate CVM age estimation method particularly around the age threshold of 18 years. This approach could feasibly extend the age range for young adults during which age can be reliably estimated.

A87 Mitochondrial DNA (mtDNA) Mutations as a New Approach for Age-at-Death Estimation

Sara C. Zapico, PhD, Smithsonian Institution, Dept of Anthropology, NMNH, MRC 112, 10th & Constitution Avenue, NW, Washington, DC 20560; and Douglas H. Ubelaker, PhD, Smithsonian Institution, Dept of Anthropology, NMNH, MRC 112, Washington, DC 20560*

After attending this presentation, attendees will consider the possibility of using mitochondrial DNA mutations as an alternative to classical anthropological methods for age-at-death estimation.

This presentation will impact the forensic science community by introducing a potential quantitative indicator of age, demonstrating its accuracy of age-at-death estimation in two Spanish populations.

Age-at-death estimation is one of the fundamental parameters in the identification of human remains, particularly in mass disaster scenarios where skeletons are often incomplete, complicating the correct identification of the victims. Teeth are frequently preserved long after all other tissues have disappeared and are often used to estimate characteristics like age-at-death.

There are several approaches to age estimation based on dental development. In forensic anthropology, the Lamendin technique and its variants are non-invasive methods of age-at-death estimation; however, these methods can only be applied to single-rooted teeth and their accuracy is not guaranteed due to differences in population-specific references. In contrast, the new methodologies for age estimation are based on the natural process of aging, which causes alterations of tissues and organs on different biochemical levels. One of these alterations is the increase in the production of free radicals with age, playing a key role in the degenerative processes of senescence. The increase in free radicals, oxidative stress, induces an accumulation of non-repaired lesions in mitochondrial DNA (mtDNA). Some studies have pointed out the relationship between mtDNA mutations and age in different tissues. These studies are potentially interesting in forensic identification because they could help to improve the estimation of age-at-death.

Since teeth are the hardest tissue of the human body and one of the most abundant types of biological remains available in forensic cases, the goal of this study is to evaluate the mutations in mtDNA from dentin and pulp and their relation with the age, and assesses the reliability of this methodology in two Spanish populations.

Thirty healthy erupted third molars from Asturias, NW Spain, and 30 healthy erupted third molars from Cataluña, NE Spain, (aged 20-70 years) were collected from dental clinics. The Smithsonian Institution's ethical committee approved all procedures related to experimentation with human subjects. The teeth were cleaned and the enamel and cementum removed. The dentin was isolated, mechanically ground, and divided in aliquots of 200mg each; pulp also was isolated. The dentin and pulp were submitted for DNA extraction and quantification. As a control of correct human DNA extraction, the Amelogenin gene was amplified. To study the mtDNA mutations, Hypervariable region 2 (HV2) of the mitochondrial D-loop was chosen. This region was analyzed by Real Time Polymerase Chain Reaction (RT-PCR). Each sample was tested in triplicate. The analysis of relative gene expression data was calculated using the $2^{\Delta\Delta CT}$ method.

Quantitative-PCR (qPCR) results were similar in the two populations. There was an age-dependent decrease in the amplification of HV2 region in dentin and some variation in pulp. Using a regression analysis, a negative significant strong linear correlation was found between the mtDNA amplification and the age in dentin, with almost the same value in both populations. In contrast, a correlation was not found between mtDNA amplification and the age in pulp. The reason for this variation is the projection of the odontoblastic processes from pulp to dentin, which houses numerous mitochondria. As a result, the majority of the oxidative stress is generated in the dentin, making it possible to relate with age.

The findings from this research provide a new quantitative tool for estimating age-at-death which, in combination with traditional age markers, could improve identification accuracy in forensic cases. Future research may be able to expand on these results, using different types of teeth, analyzing different populations, and extending the age range.

Age-at-Death, Anthropological Methods, Mitochondrial DNA Mutations

Anthropology Section - 2015

A88 A Test of the Passalacqua Sacral Age-Estimation Method in a Japanese Sample

Carrie A. Brown, MA, Joint POW/MIA Accounting Command, Central Identification Laboratory-CONUS Annex, 106 Peacekeeper Drive, Ste 2N3, Offutt AFB, NE 68113-4006*

After attending this presentation, attendees will understand the applicability of the Passalacqua sacral age-estimation method to individuals of Asian (Japanese) ancestry.

This presentation will impact the forensic science community by providing error rates for a new age-estimation method in a sample different from that of the reference method and suggesting some revisions to the method.

Age estimation is an important component of the biological profile and provides key information in the identification of unknown skeletal remains. It is more difficult to estimate age in adults, but methods that are able to combine developmental and degenerative changes appear to be more successful than those that do not. It is important to test methods developed on certain populations in different groups, as the composition of the reference sample may affect the ability to accurately estimate age. To date, there is a dearth of data in United States research that concerns individuals of Asian ancestry.

Age estimation from the sacrum has generally focused on two areas: fusion of the adjacent sacral bodies and the sacral auricular surfaces. The method developed by Passalacqua scores seven developmental and degenerative traits of the sacrum and is based on individuals of African and European American ancestry from two American skeletal collections (Hamann-Todd and William M. Bass). Fusion of the S1/S2 and S2/S3 bodies, changes of the sacral auricular surface and apices, and porosity of the sacral auricular surface are scored as 1-incomplete/absence or 2-complete/presence. S1 ring fusion is scored as 1-incomplete, 2-fused, or 3-absorbed. The resultant scores are combined to produce a sequential seven-digit code with an associated phase and descriptive statistics. Differences in ancestry and sex were not found in the reference method, but it is currently unknown whether the method can be applied to individuals of Asian ancestry.

Sacra from Chiba and Jikei Universities Medical School documented collections were scored for the seven traits described by Passalacqua as well as three additional traits: overall bone quality, changes to superior articular facets, and S1 superior vertebral border (n=205; minimum age=17 years, maximum age=95 years). Individuals were pre-selected to create a distribution similar to that of the reference sample, but age was unknown at the time of data collection. Inaccuracy, bias, percent correct for 68% and 95% intervals, and Spearman's rho for assigned phase and known age were calculated. A Kruskal-Wallis test was run to check for differences between the sexes. To test the use of a summary score (all trait scores added) versus the seven-digit code/phase system, Spearman's rho was calculated for known age and seven-trait summary score and for age and ten-trait summary score. A random sample of 35 individuals from the Chiba collection was scored again to examine intra-observer error, and Goodman and Kruskal's gamma was calculated (two trials, ten traits). Statistics were run in computing and graphics programs and R version 2.14.2.

For the Japanese sample, the method performed with an inaccuracy of 11.85 years and bias of 0.37 years, indicating a slight tendency to overage. Older phases show increased inaccuracy as compared to younger, with a tendency to underage younger individuals and overage older individuals. For all but one phase, inaccuracy was higher in the Japanese sample than the reference method. When using 68% intervals, 54.2% of the individuals in this sample were classified correctly; the percent increased to 91.7% with 95% intervals. Of the 205 individuals scored, 61 were assigned codes that were not given in the reference article. For these individuals, a higher component score was interpreted as being older and the next "oldest" code/phase was assigned. To test if this affected overall correct classification, these individuals were eliminated from calculations; correct classification remained similar at 52.1% using the 68% interval and 93.8% using the 95% interval. There were no statistically significant differences in phase assignment between males and females (p=0.36). Spearman's correlations between known age and phase, known age and seven-trait summary score, and known age and ten-trait summary score were 0.62, 0.69, and 0.76, respectively. Goodman and Kruskal's gamma values for all but one of the ten traits were 1 or very close to 1, indicating excellent agreement between trials; bone quality was the exception (gamma=0.48).

Anthropology Section - 2015

The results of this study indicate that the Passalacqua sacral age estimation method can be applied to Japanese individuals, though with slightly less accuracy than African and European American individuals. This difference may also be due to test samples performing less accurately than reference samples. The use of the 95% interval is more appropriate, but given the wide age intervals, this method should be used in conjunction with other age-estimation methods. The method is easy to apply and the use of binary scores reduces scoring discrepancies between multiple trials. Revisions to this method should consider the addition of additional degenerative traits and the use of a summary score rather than trait code.

Age Estimation, Sacrum, Error

A89 The Effects of Parturition on Pelvic Age Indicators

Rosanne Bongiovanni, PhD, University of South Florida, Dept of Anthropology, 4202 E Fowler Avenue, Tampa, FL 33620*

After attending this presentation, attendees will understand the need for consideration of parity when assessing age of the pelvis in a recent forensic sample from the United States, the necessary methods utilized on the pelvis, the process and reasoning behind the collection of data, and subsequent statistical analysis employed in this study.

This presentation will impact the forensic science community by indicating whether parturition affects an accurate assessment of age on the pelvis in a recent forensic sample from the United States and if it needs to be considered as an addition to the methods employed in human identification.

Estimating age from skeletal remains is a critical component of the biological profile of an individual. To date, there are different methods used on select parts of the skeleton to assess the age of the individual, and currently the pelvis is relied upon heavily to obtain accurate and reliable age ranges.¹⁻³ Other researchers have found that age-related changes follow different trends in males and females, with parity presented as one of the possible causes for such differences.^{1,4-6} There is reason to believe that parturition may increase the rate at which the areas of interest of the pelvis degenerate; however, this hypothesis has yet to be formally tested on a recent skeletal collection. The purpose of this study, therefore, is to assess the effects of parturition on the pubic symphysis and auricular surface and determine whether it influences the physiological age of the individual enough to cause an inaccurate estimate of the chronological age.

Data were collected from the William M. Bass Skeletal Collection located at The University of Tennessee, Knoxville. This is a collection of recent forensic skeletons with known age-at-death, ancestry, sex, and medical background. The features of the pubic symphysis were noted and matched with the best-fitting phase in both the Suchey-Brooks and Todd pubic symphysis scoring systems.^{2,7} Next, the features of the auricular surface were noted and matched with the best-fitting phase in the system presented by Lovejoy and colleagues and were individually scored, resulting in a composite score following the method proposed by Buckberry and Chamberlain.^{3,4} Therefore, others attempting to replicate this research will be able to reliably assess these areas. Time was designated at the beginning of the second and third days to employ the test-retest method to calculate the intra-observer error rate and ensure reliability of these assessments.

In this study, a statistical comparison was made between females who have given birth and those who have not to determine whether this process affects the rate of degeneration of the areas of interest of the pelvis. A transition analysis, also known as a cumulative probit analysis, was conducted on the data in order to establish the age-at-transition distributions between the stages of each age-estimation method. The results were then compared between the males and the parous and nulliparous female groups. The purpose for this comparison is to observe whether the age-at-transition distributions differ between sexes and/or the two groups, with the focus being on whether the parous group illustrates a difference in rate of degeneration, or transition to subsequent observable stages, when compared to the nulliparous group.

The study contained 434 individuals (males: 234/females: 200/parous: 157/nulliparous: 43). The data was entered into the statistical software program R version 3.0.2. The transition analysis produced significantly different results between parous and nulliparous females using the pubic symphysis but not when using the auricular surface. The current research suggests that parturition affects the pubic symphysis and not the auricular surface when determining age-at-death. Moreover, the male group and the nulliparous female group transition around the same age, while the parous females transition at an earlier age. The applicability of taking parturition into consideration when assessing the age of females for use in human identification in modern forensic cases will be discussed.

A90 Sex Estimation From the Vertebral Foramen of the Seven Cervical Vertebrae: An Analysis of Greek and Portuguese Skeletal Populations

Andrew S. Rozendaal, HBSc, Saint Mary's University, Dept of Anthropology, 923 Robie Street, Halifax, NS B3H 3C3, CANADA; and Tanya R. Peckmann, PhD, Saint Mary's University, Dept of Anthropology, MS217, 923 Robie Street, Halifax, NS B3H 3C3, CANADA*

After attending this presentation, attendees will recognize the potential value in utilizing the vertebral foramen of the seven cervical vertebrae to estimate sex of unknown individuals. Skeletal remains are commonly exposed to a variety of taphonomic processes, including destructive environmental factors, disarticulation, and scattering due to animal scavenging, which hinder skeletal sex estimation methods. The cervical vertebrae exhibit strong architectural structural integrity resulting in good postmortem preservation that increases the likelihood for successful adult sex estimation when other sexually diagnostic elements of the skeleton are absent or badly preserved.

This presentation will impact the forensic science community by providing alternative means of correctly identifying the sex of unknown individuals from the cervical vertebrae and will be useful in cases such as mass disasters when only fragmented remains are available for examination.

The purpose of this study was to understand the relationship between sex and the cervical vertebral foramen in two White skeletal populations. A total of 295 individuals (157 males and 138 females) were selected from two cadaveric collections: (1) the University of Athens Human Skeletal Reference Collection, Greece (N=135); and, (2) the Luis Lopes Skeletal Collection, National Museum of Natural History, Lisbon, Portugal (N=160). Inclusion criteria consisted of individuals from 20 to 99 years of age, the presence of at least five complete cervical vertebrae, and vertebrae free of skeletal pathologies. The maximum vertebral body height (CHT) and anterior-posterior (CAP) and transverse diameters (CTR) of the vertebral foramen were recorded for each of the seven cervical vertebrae (excluding CHT for C1). Measurements were taken from the superior aspect of the vertebral foramen using a digital Vernier caliper accurate to 0.01mm.

The data were then subjected to statistical analyses; the mean, range, and standard deviation were calculated for each vertebra. Pearson's correlation coefficients were calculated to measure the correlation between CHT, CAP, and CTR measurements and stature. Two-sample *t*-tests were used to test the presence or absence of sexual dimorphism in the Athens and Lopes collections. Two-sample *t*-tests were also used to test whether the mean vertebral measurements for males and females exhibited statistical differences between the two White populations. Canonical discriminant function coefficients were used to develop formulas to estimate sex from the vertebrae that exhibited sexual dimorphism.

The results of this investigation showed that sexual dimorphism is exhibited in the CHT and CTR measurements between males and females with means greater in the male population in all cervical vertebral segments. No statistically significant differences were observed in the CAP measurement between males and females. There were no statistically significant population differences between vertebral measurements in the Athens population compared to the Lopes populations; therefore, males and females from both populations were grouped into one large sample population.

When examining the classification results to assess which vertebrae more accurately estimated sex, a combination of all three measurements (CHT, CAP, CTR) from all seven vertebrae (C1-C7) performed best with 84.9% correct male estimation and 83.3% correct female estimation. Excluding the irregular C1 and C2 vertebrae, classification results correctly estimated males (82.9%) and females (81.7%). When removing the irregular vertebrae and the transitional C7 vertebra, C3-C6 correctly estimated males (80.2%) and females (78.2%). The strongest sexually dimorphic indicator was the CHT measurement followed by CTR in all seven vertebrae with CAP exhibiting minimal statistically significant dimorphism. Utilizing CHT and CTR measurements for vertebrae C3-C7, males and females are correctly classified with accuracies of 84.8% and 80.6%, respectively. Classification using the two measurements of the vertebral foramen (CAP, CTR) results in low accuracies for vertebrae C3-C7 with 71.3% correct male and 67% correct female estimations. The most dimorphic measurements were C1AP, C2HT, C2TR, C3HT, C5HT, C5TR, and C7TR with 79.4% correct male estimation and 84.9% correct female estimation using these seven features. Sex estimation could not be performed on individual vertebrae due to poor male and female classification accuracies that ranged from 58.9% to 74.4%.

Anthropology Section - 2015

This research has shown that sexual dimorphism is present in the vertebral foramen of the seven cervical vertebrae; however, the discriminant functions equations derived from the two vertebral foramen dimensions (CAP, CTR) are of limited use because of the low correct sex estimation accuracies. The CHT measurement must be included in the equations to achieve higher accuracies for sex estimation. Also, including all seven vertebrae in the discriminant functions will result in higher accuracies for sex estimation.

Forensic Anthropology, Sex Estimation, Cervical Vertebrae

Anthropology Section - 2015

A91 The Use of Femoral Neck Axis Length to Estimate Sex and Ancestry

Rebecca Meeusen*, 42531 Rockrose Square, Unit 302, Ashburn, VA 20148; Angi M. Christensen, PhD, FBI Laboratory, 2501 Investigation Parkway, Quantico, VA 22135; and Joseph T. Hefner, PhD, Michigan State University, Dept of Anthropology, 355 Baker Hall, East Lansing, MI 48824

After attending this presentation, attendees will be familiar with the Femoral Neck Axis Length (FNAL) measurement as well as how FNAL can be used to estimate sex and ancestry from skeletal remains.

This presentation will impact the forensic science community by providing a new, simple, reliable method of sex estimation using the FNAL measurement, including an equation that can be used to estimate sex from FNAL with ~86% accuracy.

Having multiple reliable methods of estimating sex and ancestry from various skeletal features increases the likelihood of identifying an unknown individual from skeletal remains. Measurements of the proximal femur have received some attention in the forensic anthropological literature for sex and ancestry estimation, due in part to the survivability of this region in forensic contexts as well as noted quantifiable variation. FNAL is a measurement of the proximal femur that represents the distance from the base of the greater trochanter (the point directly inferior to the greatest lateral projection of the greater trochanter) to the apex of the femoral head. FNAL and related hip measurements (typically obtained from Dual-Energy X-Ray Absorptiometry (DXA) scans) are often utilized by bone densitometrists and other skeletal health experts in assessing hip fracture risk in living individuals and have been shown to vary by sex and ancestry. This research measured FNAL directly from skeletonized remains and investigated its potential use in forensic anthropological applications to estimate sex and ancestry of unknown individuals.

FNAL was measured on 286 femora from skeletally mature adults, free of visible anomalies potentially affecting the measurement. The sample included female and male American White, American Black, and Native American skeletons. One-way Analysis of Variances (ANOVAs) were used to evaluate the relationships between FNAL and sex and ancestry. Multiple univariate Discriminant Function (uDFA) and Logistic Regression (LR) equations were calculated to test the efficacy of FNAL for sex and ancestry estimation.

A random subset of 50 femora was measured by a second observer for the purpose of inter-observer error assessment. Results showed low inter-observer error in the measurement, with a Technical Error of Measurement of 0.33mm and a Coefficient of Reliability of 0.99, indicating that the FNAL measurement is well defined, easily recognizable, and reproducible.

Significant differences in FNAL were found between females and males, with male FNAL being significantly larger than female FNAL. An LR model using FNAL and sex-pooled samples performed very well. For an individual of unknown sex and ancestry, the following LR equation is applicable: $Sex = -3.89 + (FNAL) * 0.0426$. A negative value indicates that the unknown is female and a positive value indicates that the unknown is male. Using this equation, sex will be correctly classified in ~86% of all cases.

Significant differences in FNAL were found between American Black, American White, and Native American groups, with American Whites having the largest FNAL, followed by American Blacks, then by Native Americans. Post-hoc comparisons showed that American White FNALs are not statistically different from American Black FNALs, but both are significantly larger than Native American FNALs; however, correct classification of ancestry was found to be much lower and more complex than for sex, and the value of FNAL to ancestry estimation is currently considered limited. A uDFA performed moderately well (57% cross-validated correct classification) at classifying the ancestry of males and may therefore have some utility in certain forensic contexts.

FNAL is a measurement that has not been previously utilized by anthropologists, but has been shown to vary significantly by sex and ancestry. This research shows that sex estimation using FNAL measured from skeletonized femora is highly reliable, correctly predicting sex at a rate of ~86%. Further analyses with larger samples of additional ancestral groups may help clarify the relationship between FNAL and ancestry.

These results highlight the benefits of information sharing and collaboration between forensic anthropologists and other scientists and skeletal health experts.

Femoral Neck Axis Length (FNAL), Sex Estimation, Ancestry Estimation

Anthropology Section - 2015

A92 Morphoscopic Trait Expression Within and Among Hispanic Populations

*Joseph T. Hefner, PhD**, Michigan State University, Dept of Anthropology, 355 Baker Hall, East Lansing, MI 48824; *Marin A. Pilloud, PhD*, University of Nevada, Reno/0096, 1664 N Virginia, Reno, NV 89557; *Cullen J. Black, MSc*, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853; and *Bruce E. Anderson, PhD*, Pima County OME, Forensic Science Center, 2825 E District Street, Tucson, AZ 85714

After attending this presentation, attendees will understand the frequency distribution of morphoscopic traits within two Hispanic populations, the utility of those traits for assessing ancestry at the regional population level, and the necessity of population-level ancestry assessments.

This presentation will impact the forensic science community by providing quantitative data on the distribution of morphoscopic traits for multiple Hispanic populations and a novel method for ancestry assessment using a forensic dataset.

Establishing the ancestry of human remains located along the United States-Mexico border is not a straightforward affair. The Latin American Diaspora is increasing the number of deaths along the United States southern border with Mexico, and consequently, along the major borders between Mexico and its southern neighbors. In the United States, the ancestry of these individuals is generally identified as Hispanic, a term that seemingly covers an intentionally large number of Spanish-speaking (cultural) groups, although doing so without justification in many instances. Previous authors identified craniometric differences among various populations recovered along these borders; however, limited research has focused on the differences in morphoscopic trait expression between Mexican, Guatemalan, and other Latin American groups and the utility of those traits for the assessment of ancestry.

This study evaluated population variation of eight cranial morphoscopic traits using samples of known Southwest Hispanics ($n=72$), Guatemalans ($n=106$), American Blacks ($n=146$), and American Whites ($n=218$). This study applied the Support Vector Machine (SVM) method to build a prediction model based on a sub-sample (20%) of the data; the remainder of the data was used as a test sample. SVMs are supervised learning models for data analysis and pattern recognition, useful for classification purposes. The model searches for a linear boundary (the support vector) between groups using the observations situated between groups, rather than using a centroid value (as in discriminant function analyses). When a linear boundary is not possible — which is often the case with biological data — a kernel trick is used to create non-linear classifiers to best fit the model. SVMs perform well for datasets that are non-linear, sparse, or have high-dimensionality, which are all issues that can occur when working with categorical variables in classification models.

The SVM approach effectively differentiated between the four groups with correct classification rates between 72% (Guatemalan group) and 94% (American Black group). However, when the Guatemalan and Southwest Hispanic samples were pooled, the same model correctly classified all groups with a higher degree of accuracy (American Black=96%; American White=77%; and the pooled Hispanic sample=91%). This study also identified significant differences between the two Hispanic groups in six of the eight traits using univariate statistical tests. These results speak to the unique population histories of these samples and the current use of the term “Hispanic” within forensic anthropology. Finally, it is argued that the SVM can be used as a classification model for ancestry estimation in a forensic context and, as a diagnostic tool, may broaden the application of morphoscopic trait data for the assessment of ancestry.

Morphoscopic trait analysis can be used to assess ancestry, both at the population level and using larger, geographic-based (grouped) ancestries. Although Guatemalan and Hispanic individuals differ significantly in the distribution of character states, combining these two groups under the umbrella-term “Hispanic” is useful in the United States, where ancestry assessments using broad terms are generally sufficient for the identification process.

Ancestry, Morphoscopic Traits, Support Vector Machines

Anthropology Section - 2015

A93 Estimating Ancestry From the Postcrania of Modern South Africans

Leandi Liebenberg, BSc, 18 Alice Street, The Reeds, Centurion, Pretoria, Gauteng 0158, SOUTH AFRICA; Ericka N. L'Abbe, PhD, PO Box 5023, Pretoria 0001, SOUTH AFRICA; and Kyra E. Stull, PhD, Idaho State University, Dept of Anthropology, 921 S 8th Avenue, Stop 8005, Pocatello, ID 83209*

After attending this presentation, attendees will understand postcraniometric variation among modern peer-reported Black, White, and Colored South Africans and the statistical techniques employed to identify differences and similarities within and among South African groups.

This presentation will impact the forensic science community by contributing to the knowledge of human variation within a modern South African population and by evaluating the potential of the postcranial skeleton for the estimation of ancestry.

Several successful craniometric approaches have been developed to facilitate the estimation of ancestry; however, the cranium is not always available for analysis, emphasizing the need for postcranial alternatives. The postcranial skeleton is frequently labeled as too variable and unreliable to provide an accurate assessment of ancestry. Yet numerous studies utilize the postcrania for sex and stature estimation, where the a priori knowledge of population affinity results in higher accuracy. Thus, the presence of postcranial differences observed among populations when investigating other biological parameters inherently demonstrates the potential for the estimation of ancestry. The purpose of this study was to quantify postcranial variation among modern, peer-reported Black, White and Colored South Africans. A series of 39 standard measurements were taken from 11 postcranial bones, namely the clavicle, scapula, humerus, radius, ulna, sacrum, pelvis, femur, tibia, fibula, and calcaneus. The sample consisted of 360 modern South African individuals (120 Black, 120 White, and 120 Colored) from the Pretoria Bone and Kirsten Collections housed at the University of Pretoria and the University of Stellenbosch, respectively. Group differences were explored with Analysis of Variance (ANOVA) and Tukey's Honestly Significant Difference (HSD) test. The group means were used to create univariate sectioning points for each variable indicated as significant ($p < 0.05$) with ANOVA. Where two of the three groups had similar mean values, the groups were pooled for the creation of the sectioning points. Multivariate classification models were employed using Linear and Flexible Discriminant Analysis (LDA and FDA, respectively). Classification accuracies were compared to evaluate which model yielded the best results.

The results demonstrated variable patterns of group overlap. Black and Colored South Africans displayed similar means for breadth measurements, and Black and White South Africans showed similar means for the maximum length of distal limb elements. The majority of group variation is attributed to differences in size and robusticity, where White South Africans are overall larger and more robust than Black and Colored South Africans. Classification accuracies for the univariate sectioning points ranged from 43% to 87%, with iliac breadth performing the best; however, as groups were pooled when overlap was observed between two of the three groups, the majority of the sectioning points can only classify individuals into two groups rather than three. Multivariate bone models created using all measurements taken per bone resulted in accuracies ranging from 46% to 62% (LDA) and 41% to 66% (FDA). Multivariate subsets consisting of numerous different measurement combinations from several skeletal elements achieved accuracies as high as 85% (LDA) and 87% (FDA).

Ultimately, the best results were achieved using combinations of different variables from several skeletal elements. Although both Black and Colored South Africans present with narrow diaphyses and pelvis, the longer limbs of Black South Africans distinguish them from the Colored group. Both the Black and Colored groups can be discerned from White South Africans, who have a combination of long limbs, robust diaphyses, and large pelvis. The multivariate models yielded overall better results than the univariate approach, as the inclusion of more variables is generally better for maximizing group differences. Furthermore, FDA achieved higher accuracies than the more traditional approach of LDA. Despite the significant overlap among the groups, the postcranial skeleton has proven to be proficient in distinguishing the three groups. Thus, even in a heterogeneous population, a multivariate postcraniometric approach can be used to estimate ancestry with high accuracy.

Postcraniometric, Discriminant Analysis, Human Variation

A94 Postcranial Assessment of Sexual Dimorphism Among Modern South Africans

Gabriele C. Kruger, BSc, 6 Casa Bari, 574 Jacobs Street, Gezina, Pretoria, Gauteng 0084, SOUTH AFRICA; Ericka N. L'Abbe, PhD, PO Box 5023, Pretoria 0001, SOUTH AFRICA; and Kyra E. Stull, PhD, Idaho State University, Dept of Anthropology, 921 S 8th Avenue, Stop 8005, Pocatello, ID 83209*

After attending this presentation, attendees will better understand the pattern expression of sexual dimorphism in the postcranial skeleton of modern South Africans and the effect this variation has on correct classification. Different multivariate statistical methods to estimate sex, namely Linear Discriminant Analysis (LDA), Flexible Discriminant Analysis (FDA), and logistic regression, are highlighted.

This presentation will impact the forensic science community by contributing to knowledge on variation in sexual dimorphism in the postcranial skeleton, the types of statistical analyses available to assess sexual dimorphism, and to the improvement of postcranial sex estimations.

Recently, a multivariate approach using the postcrania to estimate sex achieved higher accuracies than the commonly used cranium, thereby recommending postcranial sex estimation in forensic case analysis.¹ In South Africa, sex-estimation techniques using long bones only include univariate or bone-by-bone models, which do not acknowledge sexual dimorphism in other elements and, as expected, represent an outdated statistical approach. The purpose of this study was to evaluate accuracies of sex estimation in the postcrania of modern South Africans using multivariate statistics and to compare pattern expression of sexual dimorphism in Black, White, and Colored groups. Additionally, FDA, a fairly new method to physical anthropology, was compared to two commonly used statistical techniques (LDA and logistic regression).

A total of 360 South African Black, White, and Colored individuals (equal sex and ancestry) were assessed. Colored South Africans are a peer-reported group unique to South Africa that received genetic contributions from a number of different populations from around the world.² All skeletal material was obtained from the Pretoria Bone Collection, University of Pretoria and the Kirsten Collection, University of Stellenbosch, in South Africa. Both collections are cadaveric in origin and are mainly comprised of donated or unclaimed, albeit known, individuals.³

Symmetric percentage differences (sympercents) expressed sexual dimorphism and were compared in the three South African groups.⁴ Three classification methods assessed the 39 standard measurements taken from 11 postcranial bones. The creation of different bone models and a variety of multivariate models revealed the potential of a multivariate technique. Comparisons of LDA, FDA, and logistic regression indicated which model provided the greatest discriminatory power between sex and sex-ancestry groups.

All measurement means, except sacral breadth, were larger in males than females. South African Coloreds showed the greatest differences between the sexes for the most measurement (20 of 39). Black males and females presented with the highest levels of sexual dimorphism for 13 of 39 measurements. South African Whites only showed the highest degree of sexual dimorphism for six of 39 measurements. Overall, the most sexually dimorphic skeletal elements included the anterior-posterior and vertical diameters of the clavicle, the anterior-posterior diameter of the radius, the humeral minimum midshaft diameter, and the dorso-volar and transverse diameters of the ulna.

Multivariate classification accuracies ranged from 75%-90% (LDA) to 75%-91% (FDA and logistic regression) for individual bone models. Overall, the clavicle model classified best for FDA and logistic regression, whereas the radius classified best for LDA. Multivariate subsets (various combinations of measurements) achieved correct classifications that ranged from 85%-98% (LDA) to 88%-97% (FDA and logistic regression). For both FDA and logistic regression the "all-variable" model achieved the highest correct classifications, whereas for LDA, the subset of breadth measurements achieved the highest accuracies. When classifying into sex and ancestry, a multivariate subset using eight measurements achieved classification accuracies of 79% (FDA) and 80% (LDA).

While LDA and logistic regression produced better results for some subsets and bone models, overall FDA achieved greater accuracies. Colored males and females and Black females misclassified most often as the same sex but different ancestry groups, whereas Black males and White males and females misclassified equally into different sex and ancestry groups. Overall, White males and females had the highest correct classification rates for both sex and ancestry. Postcranial bones achieved comparable classification accuracies to morphological analysis of the pelvis and higher accuracies than metric or morphological techniques using the cranium in South Africa. The high correct classifications obtained for LDA also indicate that a custom database of postcranial data can be used with *FORDISC*® 3.0 to improve classification into sex and sex-ancestry groups in forensic case analyses in South Africa.⁵

Sexual Dimorphism, Sympercents, Flexible Discriminant Analysis

A95 An Analysis of Butterfly Fracture Propagation

*Angela Khalil, BA**, 922 Kaipii Street, Kailua, HI 96734; *David Raymond, PhD*, California State University-LA, Dept of Mechanical Eng, 5151 State University Drive, Los Angeles, CA 90032; and *Elizabeth A. Miller, PhD*, CSULA, Dept of Anthropology, 5151 State University Drive, Los Angeles, CA 90032

After attending this presentation, attendees will have a clear understanding of the initial fracture mechanism and subsequent fracture propagation of butterfly fractures (a.k.a. wedge fractures). This presentation will clarify how butterfly fractures form and where, in regard to the applied loading force, this fracture pattern initiates in moderate- to high-speed blunt impacts. Attendees will gain a greater understanding of the fundamental failure mechanisms associated with butterfly fracture patterns. Attendees will also gain knowledge on the potential use of biomechanical bone surrogates in forensic anthropological studies of blunt force trauma.

This presentation will impact the forensic science community by providing clarification on how butterfly fracture patterns are formed using an interdisciplinary approach. Combining biomechanics and forensic anthropology, this study conducted dynamic three-point bending tests on surrogate tibias to determine whether butterfly fracture patterns initiate in tension or compression. The results of the tests and analyses allowed conclusions regarding the initial fracture mechanism and the subsequent fracture propagation. This information can assist pathologists and forensic anthropologists in determining the direction of force when trauma has resulted in the formation of a butterfly fracture pattern.

Purpose: This research addresses the issue of applied loading direction, initial fracture mechanism, and subsequent fracture propagation of butterfly fractures. The purpose of this research is to identify and analyze the propagation of butterfly fractures in lower limbs initiated through blunt force trauma. The scope of this research is limited to ten surrogate tibias.

Materials and Methods: Sawbones® composite tibias were utilized for this study. These models have previously been shown to display similar biomechanical properties (stiffness, fracture toughness, and ultimate strength) as real human tibial bone. All Sawbones® tibias were medium-sized left fourth generation, which have a foam core, 9mm canal, and an overall length of 37.5cm. Tests were conducted using a dynamic three-point bending impactor designed to simulate blunt force trauma applied in a Lateral-Medial (L-M) direction to the surrogate tibias. The applied loading direction of L-M was chosen to simulate a pedestrian vs. vehicle accident, which is a common source of butterfly fractures. Each test performed was documented using a high-speed video camera at 5,000 frames-per-second. Motion analysis was performed using a marker affixed to the impactor to determine dynamic deformation of each specimen. Video was also analyzed to determine where the fracture initiated and the path of fracture propagation. A triaxial accelerometer array was affixed to the impactor for determining impact force using Newton's 2nd law. Accelerometer data were collected at 20,000 Hz and filtered using Channel Frequency Class (CFC) 1000. A photogate was used to measure impactor velocity just prior to impact with the tibia. Photographs and measurements were taken before and after each test to document resulting trauma.

Results and Conclusions: All specimens tested resulted in complete fractures. All fractures initiated on the convex side of the bending bone and were the result of tensile failure of the material. The fracture(s) then propagated toward the concave side of the bending bone on an angle of approximately 45 degrees from the long axis of the bone. This angled fracture pattern is consistent with shear failure of the material within an area of the bone experiencing high compressive stress. Completion of the propagation resulted in the classic "wing shape" seen in butterfly fracture patterns. The current study is in agreement with prior biomechanical studies, which demonstrate the initial bony failure occurs as a result of high tensile stress in the material followed by shear failure on the compressive side of the bending bone. Contrary to some previous studies, none of the butterfly fractures in this study initiated on the compressive side of the bending bone and no compressive wedge fracture patterns were observed.

A96 Fracture Characteristics of Fresh Human Femora Under Controlled Three-Point Bending

Mariyam I. Isa, BS, Michigan State University, Dept of Anthropology, 354 Baker Hall, East Lansing, MI 48824; Todd W. Fenton, PhD, Michigan State University, Dept of Anthropology, 354 Baker Hall, East Lansing, MI 48824; Trevor S. DeLand, BS, E Fee Hall, East Lansing, MI 48824; and Roger C. Haut, PhD, Michigan State University, Orthopaedic Biomechanics, A407 E Fee Hall, East Lansing, MI 48824*

After attending this presentation, attendees will better understand the relationship between controlled, experimental loads and fracture outcomes in long bone bending tests on fresh human femora.

This presentation will impact the forensic science community by contributing ground-truth data linking a specific, consistent set of loading conditions under three-point bending with bone behavior and fracture morphology.

Current literature associates long bone bending failure with tension wedge fractures, in which a transverse crack initiates at the tensile surface of a bent bone and branches as it propagates toward the impacted surface of the bone; however, numerous experimental studies of long bone bending have reported variability in gross fracture outcomes. Wedge fragments have not always been presented and in some cases researchers have reported compression wedges with the transverse crack on the impacted surface of the bone.¹⁻³ Martens reported a high frequency of compression wedges under a four-point bending configuration and Kress reported some cases of compression wedges under uncontrolled loading situations.^{1,2}

Fenton et al. performed controlled three-point bending experiments on dry human femora and consistently documented incomplete tension wedge-type fractures.⁴ Within this set of experimental impacts, the orientation of the incomplete wedge could be used to reliably determine the direction of the applied load.

The objectives of the present study were to: (1) execute controlled three-point bending tests of axial loaded, fresh human femora; (2) describe the mechanical behavior of the specimens; and, (3) identify fracture outcomes, including characteristics of the complete and incomplete fractures and gross fracture surfaces.

Six pairs of unembalmed human femora were mounted into a three-point bending fixture in a servohydraulic materials testing machine. Static axial loads simulating standing posture were applied with a spring-mounted fixture. Failure was achieved via controlled displacement of a steel anvil at midshaft, inducing three-point bending. Right femora were loaded on the posterior surface and left femora were loaded anteriorly. Following each failure experiment, specimens were grossly examined for complete and incomplete fractures and fracture surface morphology.

These controlled bending tests demonstrated variability in mechanical behavior between human subjects. Failure load ranged from 4.0 to 9.2kN. The displacement of the bone to failure ranged from 5.8 to 13.2mm and the energy to failure ranged from 15.0 to 66.3J; however, there were no significant differences in failure load, displacement, or energy between the paired anterior and posterior loaded specimens. The variation in mechanical behavior did not appear to affect the consistency of fracture characteristics.

The controlled bending tests produced consistent fracture outcomes across specimens. In each case, a short transverse crack was initiated on the tensile surface of the bone. Thus, the crack occurred on the anterior surface in all posteriorly loaded femora and on the posterior surface in all anteriorly loaded femora. Upon gross examination, the transverse fracture surface was consistently mottled and billowy. Complete and incomplete fractures branched off the transverse crack and angled toward the compressed surface of the bone, producing an incomplete tension wedge. In each case, the branch point occurred on the tensile side of the neutral axis. After the branch point, the fracture surface appeared jagged and sharp. No complete wedges presented. Complete fractures were either primarily oblique (42%) or transverse (58%). All specimens exhibited at least one incomplete fracture that curved from the branch point to parallel with the bone's long axis.

This study demonstrated that bone failure occurred in a predictable manner under controlled, experimental loading conditions. Three-point bending with axial compression produced consistent fracture characteristics, although the mechanical behavior was variable between human subjects. For each specimen, the specific orientation of fracture reliably reflected the direction of the applied load.

Anthropology Section - 2015

This work is in response to the Scientific Working Group for Forensic Anthropology (SWGANTH) Gap Analysis Report, which calls for collaborative work with biomechanists to improve current methods in trauma analysis. To this end, the Michigan State University Forensic Anthropology and Orthopedic Biomechanics Laboratories are pursuing a joint research initiative investigating the effects of specific, experimentally controlled loading conditions on fracture outcome; this presentation communicates the latest work on three-point bending of human femora. The data contributed here will help experts determine the specific loading conditions that lead to a specific set of long bone fracture characteristics.

Three-Point Bending, Blunt Force Trauma, Long Bone Fracture

Anthropology Section - 2015

A97 Atypical Skull Injuries and the Biomechanical Continuum

Brian F. Spatola, MA*, Nat'l Museum of Health & Med, 2500 Linden Lane, Silver Spring, MD 20910

After attending this presentation, attendees will have an understanding of some limitations to the standard object/weapon-centered classification scheme (sharp force, blunt force, gunshot/high velocity) used in classifying bone trauma.

This presentation will impact the forensic science community by providing a broad interpretive framework for trauma analysis of bone through the examination of examples of atypical injuries of known mechanism whose characteristics contradict or overlap with those usually associated with classic trauma classifications of peri-mortem skeletal fractures.

The goal of trauma analysis in forensic anthropology is to determine the mechanism and timing of bone trauma and to address other related medicolegal problems.¹ By applying principles of biomechanics, bone trauma can often be classified as arising from sharp force, blunt force, or gunshot/high-velocity trauma and in so doing serve an important role in guiding medicolegal death investigations; however, a significant deviation from the expected magnitude or combination of extrinsic factors (e.g., acceleration, surface area, force) involved in fracture production from that which is typically associated with a given mechanism of injury can produce confounding or equivocal wounds. In such instances, an over-reliance on weapon-centric classification can lead to misclassification or over-reaching interpretations and may affect the medicolegal determination of cause and manner of death. Therefore, trauma analysis of skeletal material may be better approached by emphasizing the continuous nature of biomechanical factors that influence wound production.^{2,3}

To demonstrate this point, gunshot injuries typically involve high-velocity penetrating injuries with classic entrance/exit defects, beveling, and possibly radiating and concentric fractures; however, in rare circumstances, intermediate targets, unexpected bullet behavior, or similar intervening forces may cause significant deceleration such that a projectile may produce a fracture pattern more typical of blunt force injury. These types of injuries were more commonly seen in the 19th century, but still occur in modern contexts.^{4,5} Similarly, blunt-edged objects traveling at sufficiently high velocity are capable of producing internal beveling defects similar to gunshot wounds.⁶ This presentation provides four cases of documented injuries that exemplify the biomechanical continuum in that the fracture patterns produced are equivocal, overlap more than one category, or are otherwise atypical of the standard classifications.

Overlapping fracture characteristics or features which “transition” between standard classifications may be observed when objects conveying certain combinations of physical (i.e., size and shape) and dynamic (i.e., velocity) characteristics impact bone. Cases that highlight the problematic nature of applying rigid typology/classification in light of the biomechanical continuum underlying wound production will be presented. While a typological and weapon-centered approach to trauma analysis is often necessary to provide useful information to medicolegal authorities, descriptions of trauma are sufficient when a classification is not forthcoming.⁷

A98 A Comparison of Radiographic and Osteological Findings in Suspected Infant Abuse Cases

Heather M. Garvin, PhD, Mercyhurst University, Dept of Applied Forensic Sciences, 501 E 38th Street, Erie, PA 16546; and Steven A. Symes, PhD, Mercyhurst College, Mercyhurst Archaeological Institute, 501 E 38th, Erie, PA 16546*

After attending this presentation, attendees will understand the pros and cons of radiographic and osteological methods of trauma evaluation in suspected infant abuse cases and the benefits of forensic anthropological analyses performed in conjunction with clinical radiographic methods. Examples will also familiarize the audience with key skeletal signatures of infant abuse.

This presentation will impact the forensic science community by supporting the need for more comprehensive osteological analyses to be performed in cases of suspected infant abuse in order to confirm and supplement clinical radiographic findings. By implementing both radiographic and osteological methods, infant skeletal trauma can be more accurately documented and interpreted, thereby contributing to accurate assessments of accidental versus non-accidental trauma and providing justice to the deceased.

Approximately 700,000 children were abused in the United States in 2012, with infants (<1 year) displaying the highest number of deaths due to abuse. Even so, infant abuse cases are rarely received by forensic anthropologists. This is due in part because forensic anthropologists are usually only consulted in the event of a death and only if it is suspected that the death included significant skeletal trauma; however, it may also reflect an assumption that the clinical radiographic analysis performed by the radiologist and autopsy conducted by the medical examiner sufficiently document all necessary trauma, eliminating the need for invasive skeletal processing and osteological analysis. In such scenarios, information vital to the investigation may go undetected.

The goal of this study was to compare clinical radiographic reports of skeletal trauma in suspected infant cases to the skeletal trauma revealed by a comprehensive osteological analysis. Radiographic and osteological findings were compared in four suspected infant abuse cases examined for this study. The limited sample size reflects the scarcity of infant abuse cases received by forensic anthropologists and should not diminish the significance of such cases. The results of the comparison reveal that in many instances, the documented skeletal trauma in the clinical radiographic reports were not as extensive as the injuries observed during the osteological analysis. Errors in radiographic reports of antemortem and peri-mortem trauma were noted (e.g., rib assignments), and smaller healing calluses on the ribs were often overlooked or not apparent from the radiographs, despite being clearly evident after skeletal processing. These inconsistencies are likely due to the imposed two-dimensionality of the radiographs and overlapping anatomical structures that obscure the injuries.

Limb fractures were well documented in the radiographic reports and in one case, the radiologist noted a recently healed fracture in the limb which was not initially visible in the osteological analyses due to the overlying periosteal reaction, but became evident as the processed bones dried out. Generally, the radiographic reports were also more successful at noting metaphyseal fractures than the osteological analyses, due to the fragility of the area and possible disturbances to the metaphyseal surface during processing. In one case, close monitoring of remains during the maceration procedure, with repeated photodocumentation during processing, revealed very distinct metaphyseal ("bucket handle") fractures that were consistent with the radiographic findings. Callus sizes, fracture direction, and evidence of re-fracturing events were also more discernible in the processed remains than radiographs.

The results of this study indicate that both radiographic and osteological analyses should be required in cases of suspected infant abuse. In addition to the clinical radiographs evaluated by the radiologists, forensic anthropologists should perform their own radiographic and photographic documentation prior to any processing, and if possible at different intervals during the maceration process. With such careful procedures, even delicate signatures of infant abuse, such as metaphyseal fractures, can be osteologically documented. It is the forensic anthropologists' responsibility to educate medical examiners in the benefits of performing a full osteological analysis. In addition, because infant abuse cases are rare occurrences in forensic anthropology, it is important for forensic anthropologists to document and share their case experiences in order to create a growing knowledge base of accidental and non-accidental trauma in infant skeletons.

Child Abuse, Infant Abuse, Radiographic

A99 A Forensic Pathology Tool to Predict Pediatric Skull Fracture Patterns: Part V — Controlled Head Drops Onto Shaped Impact Surfaces

*Caitlin C.M. Vogelsberg, MS**, Michigan State University, Dept of Anthropology, 354 Baker Hall, East Lansing, MI 48824; *Patrick E. Vaughan, BS*, Michigan State University, Orthopaedic Biomechanics Laboratories, E Fee Hall, Rm 407, East Lansing, MI 48824; *Todd W. Fenton, PhD*, Michigan State University, Dept of Anthropology, 354 Baker Hall, East Lansing, MI 48824; and *Roger C. Haut, PhD*, Michigan State University, Orthopaedic Biomechanics, A407 E Fee Hall, East Lansing, MI 48824

After attending this presentation, attendees will better understand the effects of various shaped impacters on both the biomechanics and pattern of cranial fracturing generated during controlled head-drop experiments using a developing porcine model.

This presentation will impact the forensic science community by providing baseline data regarding some of the effects of cranial impacts against various shaped surfaces and comparisons to impacts against flat surfaces presented in previous studies.

Most current literature on the analysis of blunt force trauma to the cranium cites Gurdjian et al.'s works on fracturing mechanics. Although their experimental work focused on flat surface head drops, they noted that such variables as the size, shape, and energy of the impacting object have an effect on fracturing. They also stated that "a slowly moving object, fairly sharp or pointed in contour, may cause an area of depression more or less patterned after the shape of the object;" however, fatal injuries do not always result in characteristic wounds and systematic studies regarding the morphology and mechanics of injuries resulting from non-flat surface impacts are limited.¹ Thus, there is currently little more than conjecture and anecdotal data regarding the assessment of cranial fractures resulting from impacts with shaped objects. The current study was conducted to understand some of the basic biomechanical mechanisms and cranial fracture patterns from shaped surface impacts using a porcine model.

The hypotheses of the study were: (1) heads dropped against surfaces with a large contact area would have fractures that mimic flat surface experiments with peripherally initiated linear fractures; (2) as the contact area decreased, depressed fracturing would occur; (3) at some intermediate contact size and shape, there would be a combination of depressed and linear fractures; and, (4) the energy and resulting contact force necessary to cause fracture initiation would decrease with the area of the impacting interface.

To document the cranial fracture biomechanics and fracture patterns for various shaped interfaces, heads from pigs between one and 20 days old (n=64) were dropped under controlled conditions onto 14 rigid, shaped impact surfaces.² Four impacters which simulated such objects as a table corner, hammer, etc. were chosen for closer analysis. Biomechanical data were collected during each experiment; thereafter, the heads were visually inspected for fractures, photographed, and the fracture patterns were diagrammed using previously described methods.²

The four impacters were: (1) 2" hemisphere (n=8); (2) 1/16" edge (n=9); (3) 5/8" ball bearing (n=7); and, (4) 1/4" flattop peg (n=8). Peripheral linear fractures were present on 97% of the specimens analyzed (31/32). The 2" hemisphere most resembled results seen in earlier flat surface studies and seems to represent the transition between flat and focalized surfaces as five specimens expressed both peripheral linear and area of impact fractures. As predicted, as the contact area decreased, the presence of depressed fractures increased. Depressed fractures first appeared with the 5/8" ball bearing and the impacter shape also started to become discernible. The 1/16" edge generated linear fractures that extended along the impacter's contact surface and caused creasing of the bone. The 1/4" peg produced punctures through the bone and had the highest frequency of depressed fractures at 88% (7/8).

The peak forces generated at fracture for the four impacters were: (1) 1/16" edge 424±149N; (2) 2" hemisphere 378±148N; (3) 5/8" ball bearing 186±70N; and, (4) 1/4" peg 151±69N. Those in the flat surface studies were 967±350N. These data indicate that the peak force causing cranial fracture decreased with contact area and interface shape. Importantly, the kinetic energy needed to cause fracture followed a similar pattern.

This study using the infant porcine model demonstrated that impact surface shape had an effect on fracture type and pattern. Additionally, it shows the energy and forces causing cranial fracture decrease significantly for impacts against shaped surfaces which reduce area of contact. Such basic biomechanical data may have direct relevance to human pediatric victims as forensic scientists attempt to opine injury causation in cases not involving flat impact surface conditions.

This project was supported by the National Institute of Justice, Office of Justice Programs, United States Department of Justice. The opinions, findings, and conclusions or recommendations expressed in this presentation are those of this study and do not necessarily reflect the views of the Department of Justice.

Shaped Impacters, Cranial Fracture Patterns, Bone Biomechanics

A100 Experimental and Computational Validations of the Initiation and Propagation of Cranial Fractures in the Adult Skull

*Todd W. Fenton, PhD**, Michigan State University, Dept of Anthropology, 354 Baker Hall, East Lansing, MI 48824; *Mariyam I. Isa, BS*, Michigan State University, Dept of Anthropology, 354 Baker Hall, East Lansing, MI 48824; *Patrick E. Vaughan, BS*, Michigan State University, Orthopaedic Biomechanics Laboratories, E Fee Hall, Rm 407, East Lansing, MI 48824; and *Roger C. Haut, PhD*, Michigan State University, Orthopaedic Biomechanics, A407 E Fee Hall, East Lansing, MI 48824

After attending this presentation, attendees will: (1) gain further knowledge of the initiation, propagation, and sequence of cranial fractures in experimental blunt impacts performed on adult heads; and, (2) be presented with high-speed footage confirming peripheral fracture initiation in blunt cranial impacts.

This presentation will impact the forensic science community by helping clarify contrasting data in the current literature and thereby improve the forensic investigator's ability to assess adult cranial injuries.

Gurdjian et al. suggested that impact kinetic energy and implement shape both influence cranial fracture initiation and propagation.¹ Given sufficient energy, those authors reported depressed fractures generated in areas of localized contact; however, for more distributed loads, they reported peripheral cranial fracture initiation in areas of "out-bending." More recently, Kroman et al. used high-speed photography to show cranial fractures initiating at the impact site and propagating outward.² Problematically, the Kroman et al. study was limited in scope and did not reproduce Gurdjian's experiments with respect to energy and implement shape effects on fracture initiation and propagation.

The present study's goal is to help resolve the conflicting data presented above. High-speed video was used to capture fracture initiation and propagation during blunt impacts on unembalmed adult heads. Controlled impact experiments were performed with varying energies and shaped implements to investigate the effects on cranial fracture initiation and propagation. Computational modeling was also implemented to help understand the mechanisms of fracture initiation.

Seven unembalmed adult male cadaver heads were impacted with various shaped aluminum implements attached to a 10kg mass using a custom-built drop tower. Specimens were secured in a plaster of Paris bed and impacted once onto the center of the right parietal. Three heads were impacted at varying energies using a flat, three-inch diameter implement. Two heads were impacted with a flat, one-inch square implement. The remaining three heads were impacted with a two-inch spherical, two-inch spherical, and a one-inch flat implement, respectively. High-speed cameras recorded fracture initiation and propagation at 6,600 and 10,000fps. One specimen was Computed Tomography (CT) scanned. The parietal bone geometry was utilized in a computational model to investigate the distribution of impact-produced stresses.

Video footage clearly showed peripheral initiation of linear fractures in all three impacts with the flat, three-inch circular implement, one impact with the flat one-inch square implement, and the two-inch spherical implement impact.

The results of the flat, three-inch circular impacts reflect variation in location of fracture initiation, propagation, and fracturing sequence with impact energy. In the lowest energy impact (52.5J), a single linear fracture initiated in the pterion region and propagated back to the impact site. The second impact (72.7J) produced a peripherally initiating linear fracture, followed by concentric fracture around the point of impact, and then a linear fracture propagating outward from the impact site. The highest energy impact (120.2J) produced a similar fracturing sequence with more extensive damage.

The results also demonstrated implement shape effects. One impact with the one-inch square implement produced a linear fracture initiating at the impact site and propagating outward. The other produced a peripherally initiating fracture that propagated toward the impact site. The two-inch spherical implement produced a peripherally initiating linear fracture followed by concentric fracture around the impact site. The one-inch spherical implement generated a depressed fracture.

The computational model showed a zone of circumferential-oriented tensile stresses in the parietal bone near the sutures. These stresses may generate radial-oriented fractures initiating peripheral to the impact site in areas of "outbending." With higher loads, the model indicated a zone of large circumferential and radial-oriented stress around the impact site. These stresses may generate concentric and radiating linear fractures initiating at the impact site.

The goal of this study is to address a current issue in our literature involving the location of fracture initiation and direction of fracture propagation in blunt cranial impacts. High-speed photography in the current study clearly showed differences in fracture initiation and propagation depending on impact kinetic energy and the characteristic shape of the impact interface.

A101 The Fracture Printing Interface: Development of an Automatic Classification System for Cranial Fracture Patterns

Jennifer M. Vollner, MS, 354 Baker Hall, East Lansing, MI 48824; Serhat Selcuk Bucak, PhD, Michigan State University, Dept Computer Sci & Eng, 428 S Shaw Lane, East Lansing, MI 48824; Todd W. Fenton, PhD, Michigan State University, Dept of Anthropology, 354 Baker Hall, East Lansing, MI 48824; Roger C. Haut, PhD, Michigan State University, Orthopaedic Biomechanics, A407 E Fee Hall, East Lansing, MI 48824; and Anil Jain, PhD, Michigan State University, Dept of Computer Sci & Engineer, 428 S Shaw Lane, East Lansing, MI 48824*

After attending this presentation, attendees will gain knowledge of: (1) the fracture printing interface, a user-friendly computer interface based on classification algorithms capable of automatically categorizing fracture patterns with a high degree of accuracy based on impact energy level, contact surface, and head constraint condition for a porcine model; and, (2) a prototype human fracture printing interface capable of categorizing pediatric human cranial fractures.

This presentation will impact the forensic science community by demonstrating a new system to classify cranial fracture patterns with a high degree of accuracy as validated on an experimental porcine dataset and utilized in a case-based human pediatric dataset. This presentation will introduce the medicolegal community to a fracture printing interface that can aid in the interpretation of pediatric cranial trauma.

Pediatric deaths involving cranial fracture are challenging cases for both forensic pathologists and anthropologists, as little foundational research exists on the interpretation of fracture. That difficulty in interpretation was the impetus for the current study.

A porcine dataset (n=354) has been generated through controlled biomechanical impact experiments. Algorithms have been developed in order to classify fracture patterns by impact energy level, contact interface, and head constraint condition, then incorporated into a fracture printing interface. A subset of these data (n=82) will be highlighted in order to demonstrate the automatic feature extraction and classification methods that will enable the fracture printing interface to determine injury scenarios with high levels of accuracy.

Porcine heads featured in the subset of data were dropped in controlled laboratory experiments onto a rigid aluminum surface at the center of the right parietal bone. Cranial injuries were charted and classified into low- or high-impact energy groups. Data were analyzed by age categories: young porcine specimens (1-9 days old), older porcine specimens (10-18 days old), and both age groups combined. Decision trees, using cross-validation, analyzed 51 automatically extracted features (e.g, fracture length per bone, fractures per bone, and number of initiation points) in a step-wise fashion to classify fracture patterns by impact energy level.

The result of the analysis for the young porcine specimens (n=41) was an 82% correct classification of fracture patterns into energy levels based on the number and length of occipital fractures, number of fracture initiation points, and length of diastatic fractures. The older porcine specimens (n=41) were classified with a 95% accuracy based on the total length of fractures in the right parietal and the number of fractures on the skull. When the two age groups were combined, the dataset (n=82) was classified with an 87% accuracy, based on total length of right parietal fractures and the number of fracture initiation points.

These algorithms, along with others developed on the larger dataset, have also been integrated into a user-friendly fracture printing interface in which fracture pattern features are automatically extracted and are used to predict any or all of the following variables: impact energy level, contact surface, and/or head constraint condition.

The automatic feature extraction algorithms developed from the “ground truth” porcine data have been applied to human cranial fracture data (n=106) collected from death investigation offices across the country. Manually-drawn pediatric cranial fracture diagrams were uploaded into the human-specific interface which automatically extracted fracture features such as fracture length, number of fractures and type of fracture. These features were used to classify an individual case as a homicide or accident; accuracy rates are determined by the autopsy ruling. Currently, the algorithms classified with an 84% accuracy using decision trees. More data is necessary to classify fracture patterns into specific injury categories and improve the classification algorithms.

The overall vision of this work is the dissemination of the fracture printing interface which will provide practitioners with a tool that digitally uploads a pediatric cranial fracture pattern and statistically analyzes the pattern to predict the energy level and the impact surface of injury.

A102 Healing Rates of Antemortem Injuries to Bone

*Lara E. McCormick, PhD**, 803 W Alabama Street, #7, Houston, TX 77006; and *Jennifer C. Love, PhD, OCME*, 401 E Street, SW, Washington, DC 22024

After attending this presentation, attendees will be knowledgeable concerning guidelines used by radiologists for establishing a time-since-injury in healing and healed wounds, identify how these standards can be adapted for anthropological casework, be aware of discrepancies and issues when using radiological standards in anthropological casework, and understand a need for creating a set of guidelines by anthropologists for use in anthropological casework.

This presentation will impact the forensic science community by presenting the results of a pilot study demonstrating that radiological guidelines for healing rates in bone underestimate and overestimate healing times when the bone is examined macroscopically rather than radiologically.

An estimation of the length of time elapsed since an episode of trauma has occurred has importance within a medicolegal context. This is particularly true in cases where traumatic events may have multiple episodes, commonly seen in cases of domestic abuse, child abuse, and abuse of the elderly, where medical documentation of previous injuries may not exist or be accessible. Radiologically, guidelines established for healing rates are based upon the appearance of the following characteristics: resolution of soft tissues, subperiosteal new bone formation, loss of fracture line definition, soft callus formation, hard callus formation, and bone remodeling. These guidelines were developed using healthy children of various ages and are adjusted based on a practitioner's experience when examining healing or healed trauma in adults. Radiographs may not reveal a fracture clearly, depending upon the exposure, position of the individual, and location of the body. The rate of healing of a particular bone is also dependent upon the age of the individual, health of the individual, extent of injury and re-injury events, in addition to variability in healing rates throughout an individual's skeleton.

These case studies represent a pilot study conducted on individuals autopsied at the Harris County Institute of Forensic Sciences between 2004 and 2014 with medical documentation of antemortem injuries. The case studies represent 20 subadults and adults, ranging in age from one month to 91 years of age, with medical documentation concerning when antemortem injuries occurred and the extent of said injury. Cases of known injury dates in the medical examiner system are few. This presentation will showcase a series of case studies of bone healing with documented dates of injury. The cases provide an overview of healing rate variation observed in subadults and adults. The cases represent a failure in using radiological estimates and a tendency to either underestimate or overestimate time elapsed since occurrence of injury when radiological estimates are applied to dry bone. Anthropologists commonly state that gross evidence of healing is an indication that a fracture is at least two weeks old; however, early response in children is seen as early as three days after an injury occurs. This study demonstrates the need for the creation of guidelines for healing rates using macroscopic examinations of bone tissue. Macroscopic, rather than radiologic, standards will allow anthropologists to make a more complete determination of antemortem injuries.

Antemortem, Healing, Fracture

A103 Sex Differences in Measures of Bone Remodeling

Victoria M. Dominguez, MA*, Ohio State University, Division of Anatomy, 1645 Neil Avenue, Columbus, OH 43210; and Christian Crowder, PhD, Harris County Institute of Forensic Sciences, 1885 Old Spanish Trail, Houston, TX 77054

After attending this presentation, attendees will appreciate the complexity of evaluating sex-related differences in bone remodeling and how identifying these differences may improve methods of histological age estimation. In addition, attendees will learn how variable selection may mask or expose remodeling differences associated with intrinsic factors such as sex and age.

This presentation will impact the forensic science community by demonstrating the need for in-depth analysis of histological variables to determine when and why sex differences in histological variables occur. This will hopefully result in more sex-specific research to improve the accuracy of histological methods.

Estimating adult age is problematic due to biological variability in skeletal age indicators and their differential response to intrinsic and extrinsic factors during life. Histological methods of age estimation are based on bone turnover, which is argued to occur at a predictable rate; however, the literature provides conflicting data. One issue is the existence of sex differences in histological variables and the use of sex-specific age-prediction equations. Considering skeletal physiology and the interplay with biocultural factors, one appreciates the dynamic nature of bone remodeling that may produce or extenuate histological differences between males and females. As remodeling is systemic and not bone specific, it is a fair assumption that sex-specific equations should be used to improve the accuracy of histological methods. The goal of this research is to examine femoral cross-sections for sex-related differences in selected histological variables.

The sample includes femur cross-sections from 321 individuals of known age (167 males, 154 females). The following variables were collected: (1) Surface Area (Sa.Ar.) per mm²; (2) Intact Secondary Osteons (N.On.); (3) Fragmentary Secondary Osteons (N.Fg. On.); (4) Intact Secondary Osteon Density (OPDI) per mm²; (5) Fragmentary Osteon Density (OPD_f) per mm²; (6) Osteon Population Density (OPD): sum of OPD_i and OPD_f; (7) Mean Osteonal Cross-Sectional Area (On.Ar) per mm²; and, (8) Mean Anterior Cortical Width (Ant.Ct.Wi.) per mm².

Histomorphometric data collection protocols developed by Crowder and Dominguez were utilized.¹ Osteon areas and cortical widths were calculated using imaging software. Statistical analyses were performed in a statistical analysis software using variables 4–8.

The variables were tested using a Multiple Analysis of Covariance (MANCOVA), with sex as the independent variable and age as the covariate. Results showed both age and sex are significant overall ($p=0.000$); however, Analysis of Covariances (ANCOVAs) revealed that while age and sex were significant for OPD_f (both $p=0.000$), Ant.Ct.Wi (both $p=0.000$), On.Ar ($p=0.000$ and $p=0.001$, respectively), and OPD (both $p=0.000$), sex was not significant for OPD_i ($p=0.928$). Pairwise comparisons revealed females tended to have significantly higher OPD_f values, as well as significantly lower Ant.Ct.Wi and On.Ar measures than males. Correlation statistics indicate differences in variable strength with age between the sexes.

Overall, the results indicate that the tested variables demonstrate relationships with age; however, age and sex effects between variables are not consistent. Regardless, it is reasonable to conclude that sex-specific regression models are warranted. The ANCOVA results and the difference in correlation strength for OPD_i between males and females, with females showing a weaker correlation to age, suggest that age-related turnover events are best expressed by OPD_f, especially in females. Increasing OPD is coupled with reduced cortical bone thickness over time, with females demonstrating greater loss. Future analysis will include a relative measure of cortical thickness to control for size, which likely amplifies differences. Current literature disagrees about whether sex differences in osteon size exist. This research indicates that On.Ar differs significantly by sex; however, the relationship with age and sex is unclear. Young females tend to have larger mean On.Ar. when compared to males, which may relate to age of parity; however, in older age cohorts, females demonstrate smaller On.Ar compared to males.

Sex differences observed in histological variables likely relate to biological factors involving the endocrine system that affect bone turnover in the female skeleton. This research demonstrates that evaluation of sex differences in bone turnover should be considered in histological studies. Applying concepts of skeletal physiology and remodeling theory to histological observations will hopefully improve the accuracy of estimating age in adults.

A104 The Utility of Radiographs of the Proximal Femur in Positive Identifications: Establishing a Standard and Minimum Number of Concordant Points

*Ashley B. Maxwell, MA**, 18002 Allison Park Place, Apt 312, Tampa, FL 33647; *Ann H. Ross, PhD*, North Carolina State University, Sociology & Anthropology, Campus Box 8107, Raleigh, NC 27695-8107; and *Alicja K. Lanfear, PhD*, Middle Tennessee State University, Dept of Biology, Box 60, Murfreesboro, TN 37132

After attending this presentation, attendees will gain a better understanding of the validity and reliability of using antemortem and postmortem radiographs of the proximal femur in positive identifications. This research utilized a novel method in the analysis of radiographs for positive identification: classification decision trees. As a result, associated probabilities and the variance of those probabilities based on the quality and other identifying factors of the individuals and radiographs will be presented. This is of significance to forensic practitioners not only in the field of anthropology but to any forensic practitioners involved in ascertaining the identity of victims.

This presentation will impact the forensic science community by providing a standard for analysis and the minimum number of concordant points with associated probabilities needed to make a positive identification based solely on femoral radiographs in the event that other methods of identification are unavailable.

The 2009 National Academy of Sciences Report, *Strengthening Forensic Science in the United States: A Path Forward*, and the 1993 *Daubert* ruling have set the precedent for a need for more statistically valid and reliable methods for positive identifications. This includes developing testable standards for the use of radiographs for positive identifications. Clinical radiographs of the proximal femur are common, as they are often used to diagnose hip diseases and other disorders. In addition, the femur is a dense bone that preserves well in both archaeological and forensic contexts, and previous research has shown that bone density distributions of the proximal femur are unique, as they are based on musculoskeletal loading. Thus, this skeletal element can be utilized in cases where other skeletal elements have not been preserved and/or are damaged.

At present, there are no standards for the number of concordant points needed for positive identifications using the proximal femur. Therefore, the purpose of this study was to examine the morphology of head, neck, greater trochanter, and lesser trochanter of the proximal femur in a sample of 49 antemortem and postmortem pelvic radiographs of known individuals from the North Carolina (NC) Office of the Chief Medical Examiner to: (1) evaluate the uniqueness of these traits; and (2) establish the minimum number of concordant points necessary to make a positive identification with associated probabilities. Twenty-three identified individuals had both antemortem and postmortem radiographs. To represent the unknown or “no match” sample, either an antemortem or postmortem X-ray was compared to a randomly selected individual from the sample.

Classification decision trees, a robust data mining technique, were used to explore patterns and relationships. For categorical data, a G^2 or the likelihood-ratio chi-square was computed and used for multi-level split of the data. The classification tree results using the femoral head and neck show that if there is one or more femoral head concordant characteristics, the probability of the individual being correctly matched or positively identified is 93%. If there is also a concordant femoral neck trait, the probability of correctly matching or positively identifying an unknown decedent is 97%. Results for the femoral greater and lesser trochanter show that if there is one or more femoral greater trochanter concordant characteristic the probability of the individual being correctly matched or positively identified is 76%. If there are also two or more concordant femoral lesser trochanter traits, the probability of correctly matching or positively identifying an unknown decedent is 93%. Thus, the results indicate that two or more concordant points are needed in order to have a probability of a correct identification above 90%.

A105 Dental Cementum Increment Analysis Can Determine Four Seasons at Death

Vicki Wedel, PhD*, Western University of Health Science, Dept of Anatomy, 309 E 2nd Street, Pomona, CA 91766; and Kenneth P. Hermesen, DDS, Creighton University, School of Dentistry, 2500 California Plaza, Omaha, NE 68178

After attending this presentation, attendees will have developed an understanding of how dental cementum increment analysis can yield specific season-at-death estimates.

This presentation will impact the forensic science community by a novel forensic method which can be developed and refined with continued investigations.

Forensic anthropologists and bioarchaeologists are increasingly using Dental Cementum Increment Analysis (DCIA) to determine season-at-death. They are using the method of Wedel, which demonstrated that DCIA could correctly sort 112 donated teeth by the season in which they were extracted (a proxy for death) with 99% accuracy.¹ The two broad seasons into which DCIA sorted the teeth were April to September and October to March. Wedel et al. validated the 2007 results, achieving a 94% accuracy rate in correctly determining season-at-death in 467 teeth donated by patients of Creighton University's School of Dentistry.² DCIA has now successfully been used in forensic cases (Wedel et al. 2013) and is being used in various other projects, including one using DCIA to determine whether skeletal remains are evidence of a historical epidemic.

In this project, 100 teeth were chosen from the combined 2007 and 2012 samples to test the hypothesis that the two broad seasons could be separated into four. This study used the same method Wedel used to demonstrate that the width of cementum increments or annulations become thicker from season's beginning to end.^{1,2} One hundred transverse tooth root thin sections that had previously been prepared for cementum increment analysis were randomly chosen and new photomicrographs were taken. These thin sections had been prepared using the following method: each tooth had been cleaned, embedded in epoxy under vacuum pressure, and sectioned at the middle-third of the root. The thin section had been mounted to a petrographic glass slide, then ground and polished to ~100 microns, viewed under a transmitted polarized light microscope, and photographed using a digital camera mounted to the microscope. The photomicrographs were imported into Adobe® Photoshop® where the color of the outermost increment was determined (translucent for spring/summer and opaque for winter/fall) and its pixel width measured. The pixel width of ten other increments of the same color were measured and their widths were averaged. The outermost increment's pixel width was divided by the average pixel width of like increments to derive percent increment completion.

A statistically significant correlation between the number of days a tooth was into its given season and its width ($p > 0.001$) was discovered. The percentage of full-thickness increments range in width from 2% to 98%, and these percentages strongly correlate the number of days into the season. With this solid data, this study rejects its null hypothesis that seasons of death cannot be further narrowed from six-month time periods to smaller ones and support its hypothesis. If a cementum increment is 50% as thick as the average of its like bands, it can be determined during which month(s) 50% of the given season has passed. Fifty-percent completion for a spring/summer band places the date of death halfway between April and September, therefore the end of June/early July. Law enforcement can then be informed that the individual died in the summer, rather than spring/summer as the 2007 study specified.

The full potential of DCIA has not been reached. Science has demonstrated that cementum increments can be counted in pairs and added to the age at which the tooth was known to erupt to yield an age-at-death estimate. The results of this study indicate that the outermost cementum increment can help estimate season-at-death more specifically than the spring/summer and fall/winter seasons. DCIA can be used to correlate cementum increments in a tooth root to which of the four calendar seasons the death occurred. During this presentation, the utility of this method in forensic cases will be demonstrated and a course charted indicating where research on cementum increments will lead.

Anthropology Section - 2015

A106 An Updated Validation Test of a Computer-Automated Short-Listing Tool for the Radiographic Identification of Human Remains

Susan Steele D'Alonzo, MA, JPAC-CIL, 310 Worchester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853-5530; Pierre M.M. Guyomarc'h, PhD, University of Bordeaux, UMR 5199 PACEA - A3P, Bordeaux 33000, FRANCE; John E. Byrd, PhD, 95-033 Hokuwa Street, #51, Mililani, HI 96853-5530; and Carl N. Stephan, PhD, The University of Queensland, School of Biomedical Sciences, Saint Lucia, Queensland 4072, AUSTRALIA*

The goal of this presentation is to report on an updated and expanded validation test of the Clavicle Matching Program (CMP), a semi-automated computer capability that employs Elliptical Fourier Analysis (EFA) to generate a short-list of individuals with high-match potential based on quantified clavicle shape.

This presentation will impact the forensic science community by demonstrating the usefulness of this capability for searching large-scale radiograph assemblages such as the collection of chest radiographs held by the Joint POW/MIA Accounting Command-Central Identification Laboratory (JPAC-CIL) for United States soldiers who fought in WWII, Korea, and Vietnam.

The validation test employed in the original study concerned 17 test skeletons and a chest radiograph assemblage of 409 individuals. The current validation test is considerably larger, comprising 30 skeletons and the full 7,362-person assemblage of Korean War-era chest radiographs currently held by the JPAC-CIL.¹

To conduct the test, the clavicle outlines from each of the antemortem images in the reference databank were manually traced using Wacom® touchscreen tablets. The clavicles of each test skeleton were 3D laser-scanned and inputted into the software, which generated four shadowgrams for each clavicle to compare to the chest radiograph dataset using Elliptical Fourier Analysis (40 harmonics x 4 coefficients each=160 Fourier descriptors per clavicle). Using the sum of the squared differences for the Fourier descriptors, the computer then ranked all individuals in the reference databank according to their morphological similarity to the inputted skeleton.

Each search against the reference dataset of 7,362 individuals took less than 70 seconds to complete. Results for the large-scale test indicate that the correct match was included in the short-lists of the top 5% of the antemortem reference sample 57% of the time, and in the top 25% of the lists 80% of the time. This performance is slightly less than that observed for the 409-person database originally reported; however, the utility of the method is still retained and is high given the 18-fold increase in the reference sample size.¹ For cases that lack contextual information, this helps narrow a potentially lengthy candidate list quickly and effectively. Since the original validation study, the CMP has facilitated the identification of several previously unaccounted for individuals from the Korean War and has the potential to further facilitate identification of several hundred still unaccounted-for United States service personnel interred at the National Memorial Cemetery of the Pacific.

Anthropology Section - 2015

A107 Unidentified Border Crosser Deaths in Arizona: Expanding Intra-State Collaborative Efforts in Documentation and Representation

Ashley E. Kendell, MA*, 655 Auditorium Drive, 355 Baker Hall, East Lansing, MI 48824; Julie M. Fleischman, MS, 6138 Farrington Court, #D10, East Lansing, MI 48823; Christen C. Eggers, MS, 701 W Jefferson Street, Phoenix, AZ 85007; and Laura C. Fulginiti, PhD, Forensic Science Center, 701 W Jefferson, Phoenix, AZ 85007

The goals of this presentation are twofold: first, to implement changes in the data-recording methods currently employed at the Maricopa County Office of Medical Examiner (MCOME) in an attempt to create a more functional approach to identifying Unidentified Border Crossers (UBCs); and, second, to create a working database and facilitate the mapping of UBC deaths in Maricopa County. The present research project was inspired by the 2014 American Academy of Forensic Sciences (AAFS) Scientific Session entitled, “*Medicolegal Investigation of Migrant Deaths.*”

This presentation will impact the forensic science community by supplementing the data presented by the Pima County Medical Examiner’s Office at the 2014 AAFS Meeting. This presentation will illustrate the growing number of UBC deaths occurring north of Pima County and, in so doing, will provide a more comprehensive picture of this important anthropological issue within the state of Arizona.

As previously reported at the 2014 AAFS Annual Scientific Meeting, the issue of UBC deaths in Arizona is a growing concern, largely reinforced by United States border enforcement policies which make crossing increasingly difficult and dangerous.¹ To date, thousands of foreign nationals have died during their attempts to cross the United States-Mexico border. An even greater tragedy is the increasing number of migrants who are not repatriated to their families because personal identifications cannot be made. Currently, the MCOME is in possession of more than 200 unidentified individuals, more than half of whom are presumed to be UBCs.

The primary goal of this study was to evaluate UBC deaths in Maricopa County. Using the PCOME recording system as an example, this study developed criteria for inclusion into the UBC database. These criteria include only individuals found in desert areas and whose biological profiles indicated potential Hispanic ancestral origins. Once cases were classified as potential UBCs, the following data were collected based upon the information requested by the Human Borders Geographic Information Systems (GIS) Project: (1) age at death; (2) sex; (3) date of death/recovery; (4) cause of death; (5) body condition; (6) presumptive identification (e.g., identification cards found on the body); (7) location description including Global Positioning System (GPS) X and Y coordinates; and, (8) any related case numbers (e.g., individuals traveling in a group).

Data were collected for 113 probable UBC cases. All data were extracted from MCOME case files dating from 1981 to 2014. The general trend in UBC cases indicates a gradual increase from 1981 to the present. In 1981, the MCOME analyzed one case of a potential UBC. In 2013, the office analyzed a total of 11 UBC cases. Of the 113 total cases evaluated for the study, four individuals were anthropologically determined to be female and three were probable females. The remaining 106 individuals were males. Age estimates for UBCs were varied but the majority fell between the ages of 20 to 50 years of age with few individuals under 20 or over 50 years old. These cases varied taphonomically from fresh to decomposed or skeletonized/mummified. All individuals included in the study are in the process of being added to The Map of Migrant Mortality, a GIS-based tool containing spatial data related to migrant deaths that was created in conjunction with the Human Borders Project and the PCOME.

In documenting UBC deaths in Maricopa County, the MCOME has extended the northern reaches of migration routes across the state of Arizona, thereby further contributing to the overall awareness of the border crossing issue. It is anticipated that this research will improve the documentation and processing of UBCs at the MCOME and, in turn, will aid in the personal identification of UBCs, allowing for the return of many unknown decedents to their loved ones in foreign countries. By employing the Pima County model, the hope is to demonstrate the importance of intra-state anthropological and pathological collaboration in identification efforts.

A108 Odontometric Differentiation Between Southwest Hispanics, Native Americans, and European Americans

Donovan Adams, BS*, 35 Harold Street, Apt 3, Roxbury, MA 02119; James Pokines, PhD, Boston University School of Medicine, Dept of Anatomy & Neurobiology, 72 E Concord Street, L1004, Boston, MA 02118; Jonathan D. Bethard, PhD, Boston University School of Medicine, Dept of Anatomy & Neurobiology, 72 E Concord Street, L1004, Boston, MA 02118

After attending this presentation, attendees will understand the procedures and value of using odontometrics for the purpose of ancestry estimation in a sample of modern American populations.

This presentation will impact the forensic science community by presenting a method of ancestry estimation valuable when cranial morphology and metrics are insufficient for analysis or supplementary techniques must be utilized.

Data were collected from $n=571$ dental casts from a modern North American population from the James K. Economides Collection at the Maxwell Museum at the University of New Mexico. Buccolingual and mesiodistal dimensions of 16 permanent teeth were taken on the left side of the dental arcade. Cervical dimensions were also examined for utility, but many were found to be difficult to obtain due to the replicated soft tissue in the cast and while teeth were still in position. Teeth examined were the maxillary central incisors, canines, third premolar, and first molar and the mandibular lateral incisors, canines, third premolar, and first molar. The teeth chosen follow the morphogenetic field theory of Dahlberg, where these teeth are least variable in size and morphology.¹ Arch dimensions and overall tooth composition were also examined by measuring arch width between antimeres, arch depth, and the proportional make-up of each tooth class in the overall dental arcade. For the purposes of this investigation, only teeth displaying little attrition and no pathological conditions were used for all measurements, and only teeth in correct alignment were used for dental arcade measurements.

Four populations were examined: (1) Southwest Hispanics ($n=202$); (2) Native Americans ($n=161$); (3) European Americans ($n=165$); and, (4) Asian Americans ($n=43$). According to the mean results, Native Americans had the largest dimensions and European Americans had the smallest. Due to the nature of the small Asian American sample, interpretation of the means must be approached with caution. Southwest Hispanic measurements were consistently in the middle, except for the cervical buccolingual diameter of the maxillary canine, the buccolingual diameter of the mandibular incisor, both buccolingual diameters of the mandibular canine and premolar, and the maxillary incisor composition, where they were the largest. Hispanics had the largest arch depth, whereas Native Americans had the smallest. The means for all arch width measurements (width between key teeth antimeres) were largest for Native Americans and smallest for European Americans, except for the mandibular molars, where Hispanics had the largest width and European Americans had the smallest.

Multivariate Analysis of Variance (MANOVA) indicated statistical significance in most variables for sexual dimorphism, except for the cervical and crown buccolingual measurements of the mandibular incisor, the maxillary premolar composition, and the mandibular incisor arch width. For all variables, the means for males ($n=255$) were larger than females ($n=316$). Statistical significance was found in many variables for ancestry, except for the buccolingual cervical and crown measurements of the maxillary incisor, the mesiodistal measurement of the maxillary molar, the cervical buccolingual measurement of the mandibular incisor, the cervical buccolingual measurement of the mandibular canine, the buccolingual measurement of the mandibular premolar, the maxillary molar composition, mandibular premolar and molar composition, and both maxillary and mandibular arch depths. Definite clustering is present of individuals around a centroid, indicating some utility in ancestry estimation. When sex is known, an increased number of clusters occur, differentiating between males and females of each population, indicating an important contribution of sex as a variable in odontometric ancestry estimation.

The findings in the current study indicated possible utility in ancestry estimation techniques in the efforts of undocumented border-crosser identification and other forensic casework. Distinct patterns are visible with respect to tooth size and palate shape. Use of odontometrics may provide supporting evidence for other methods of ancestry estimation and as a valuable method when teeth are the best surviving elements.

Odontometrics, Palate Shape, Ancestry Estimation

Anthropology Section - 2015

A109 The Joint Prisoners of War/Missing In Action (POW/MIA) Accounting Command Solvability and Resolvability Rating Project

Ivett Kovari, PhD, 445 Seaside Avenue, Apt 4302, Honolulu, HI 96815*

After attending this presentation, attendees will better understand the scope, objectives, and applications of the Joint POW/MIA Accounting Command (JPAC) Solvability and Resolvability Rating Project. This system could easily be applied to collections of cold cases in police jurisdictions or universities that remain unsolved and, with relevant modifications, it could also be applicable for other countries' military losses.

This presentation will impact the forensic science community by familiarizing those in the field with the stand-alone multidisciplinary Solvability and Resolvability Rating Project created at JPAC. The advantages of combining anthropological analysis, archaeological research, archival studies, and military history will be presented through the introduction of the Solvability and Resolvability Rating System. The relevance of the rating system lies in the established conjunction of the circumstantial information (circumstances of loss) and the biological information available. The takeaway of the Solvability and Resolvability Rating System is to create a product that is an objective, quantitative assessment of each case. This presentation will put forth the definitions, the structure and elements of the scoring system, and the outcome of the project.

The JPAC Standard Operating Procedures determines that all missing persons are equal: "The importance of any missing person, regardless of the conflict or circumstances of loss, is equal to that of any other missing person." The Solvability and Resolvability Rating Project comprehensive databases, therefore, include all missing persons and unknown remains inclusive of all relevant conflicts. The project established routine procedures to ensure the information in the database is accurate, verifiable, and up to date. The system coordinates and standardizes structure and content with all relevant databases maintained by other members of the accounting community. It ensures that each database is available to relevant members of the accounting community inside and outside of JPAC. The project maintains the database to ensure that the information is not only kept up to date, but that the underlying structure and methodology of the database is tamper-proofed for posterity.

The "Solvability Rating" applies to missing persons only. It is defined as a quantitative expression of the probability that a missing person may be accounted for using existing circumstantial information, scientific evidence, and forensic testing techniques. The Solvability Rating is a quantitative expression of numerous analytical issues, including the probability that a missing person's remains may be located, the potential for a site to yield remains, the quantity and quality of the antemortem records for each missing person, and the probability that remains, if recovered, may be identified using existing forensic testing methods. The rating is based on a scoring system of the accessible information cited above. The Solvability Rating serves three principal purposes: (1) to increase the efficiency and effectiveness of investigation and recovery efforts (by minimizing the risk that JPAC will allocate resources toward recovery of remains associated with missing persons whose antemortem records and site potential lack sufficient probability for the purpose of identification); (2) to pinpoint the sub-optimal informational, evidentiary, or geographical elements that must be acquired or improved for missing persons whose Solvability Rating is insufficient, incomplete, or otherwise non-adequate; and, (3) to consolidate the Solvability Rating for all missing persons.

The "Resolvability Rating" applies to cases believed to be missing persons buried as unknowns in National Memorial Cemeteries in the United States as well as in American Battle Monument Cemeteries overseas. It is defined as the quantitative expression of the probability that the forensic testing of human remains will produce probative information that will contribute to the identification of an unknown person. The Resolvability Rating is an assessment of the postmortem biological evidence associated with each unknown. Besides the determination of the probability, the purpose of the Resolvability Rating is to contribute to the JPAC program of disinterments for the purpose of identification and to consolidate the Resolvability Rating for all unknowns.

The Solvability and Resolvability Rating Project's intent is to support the Accounting Community's mission by supporting the Defense POW/Missing Personnel Office, the JPAC Research & Analysis Group, the JPAC Directorate of Operations, and the analysts of the JPAC Central Identification Lab. The project creates economies of scale and assists to optimize resource allocations as and when required. Dr. Kovari inherited the Solvability and Resolvability Project from Dr. Paul M. Cole. Dr. Cole has given his permission and consent that any text concerning this project written by him may be used by Dr. Kovari as she sees fit, without specific attribution.

A110 Theory in Forensic Anthropology: A Retrospective and Look Forward

Donna C. Boyd, PhD*, Radford University, Forensic Science Institute, PO Box 6939, Radford, VA 24142; and Charles C. Boyd, PhD, Radford University, Dept of Anthropological Science, Radford, VA 24142

After attending this presentation, attendees will be able to recognize forensic anthropology theory, trace its origins, understand the different levels at which it operates, be aware of its applications in forensic anthropological analyses, and explain how it directs, influences, and stimulates research.

This presentation will impact the forensic science community by illustrating the vibrant but, at times, unrecognized theoretical underpinnings of the science of forensic anthropology and how they direct and influence data collection and analysis in every area of specialty within the discipline.

Theories are basic premises or postulates that can be used to explain and predict empirical phenomena. It is important to explicitly acknowledge and study theory because it provides a foundation and direction for research and the application of knowledge generated by research. It also dictates how a discipline is perceived by insiders, outsiders, and the law. The types of theory applied to research directly influence the results which are obtained. The types of research which are conducted in forensic anthropology enhance its theoretical development and ultimately strengthen the scientific foundation of the discipline.

Although the legitimacy of forensic anthropology as a science and a discipline has recently been questioned due to its perceived lack of a grounding body of theory, theoretical frameworks have clearly been present since publication of the first textbooks in forensic anthropology. Although Krogman and Stewart do not explicitly discuss theory, reliance on it is clearly evident throughout their books.^{1,2} Each credits human variation as the foundation for techniques in forensic anthropology, but neither directly addresses the explanatory nature of a theory of human variation for the human skeleton. They see the lack of precision in explaining human variation as precluding “consideration of forensic anthropology as an exact science.”²

This absence of an explicit acknowledgement of theory has continued. A review of all forensic anthropology research articles, case studies, and technical notes (N=498) from the *Journal of Forensic Sciences* and all major forensic anthropology textbooks published over the past 20 years (1995-2014) was undertaken by this study to examine evidence for and trends in theoretical development and its application in the discipline. Variables scored include presence/absence of a theoretical framework or hypothesis and characterization of theory type and level. Results indicate that while approximately 83% of *Journal of Forensic Sciences* publications relied on some aspect of theory, only 36% of these articles explicitly recognized the theoretical basis for the presented research. Only one article discussed the concept of theory in forensic anthropology as a whole. Likewise, although one forensic anthropology textbook had “theory” in its subtitle, none devoted more than a few paragraphs to the explicit theoretical basis for the discipline.

This theoretical grounding in forensic anthropology was evident on many levels, including high-level (micro and macro-evolutionary theory, including natural selection), middle-range (taphonomic, agency, behavioral theories), and lower-level (methodological, recovery, statistical theories), although these were rarely explicitly discussed. For example, identification of decedents through their biological profile and antemortem conditions relies on the high-level evolutionary principles of human variation as well as statistical (including Bayesian) theories. Trauma analysis borrows from theoretical principles of biomechanical engineering and physics. Recognition and differentiation of postmortem processes derive from middle-range taphonomic theories, while forensic archaeological search and recovery draw from lower-level theoretical principles from geology, geography, agency theory, and abductive reasoning. Trends observed over time include an increased focus on trauma and morphometric analyses, accompanied by discussions of the theoretical basis for these analyses.

Examining the concept of theory in forensic anthropology illustrates the three 2015 American Academy of Forensic Science (AAFS) planks of honoring our mentors and traditions, learning from each other, and stimulating our future. Theory does indeed form a strong foundation in forensic anthropology, albeit often unrecognized. The broadness of this field dictates that this theory is interdisciplinary and multidisciplinary, deriving from a variety of sources and operating at many levels. This eclectic theoretical basis enriches rather than weakens this discipline. Recognition of the ideas, models, and concepts that form the basis of how forensic anthropologists see their subject matter is vital for stimulating future growth of the discipline.

Theory, Forensic Anthropology, Retrospective

Anthropology Section - 2015

A111 Subjective With a Capital “S”? Issues of Objectivity in Forensic Anthropology

Allysha P. Winburn, MA, C.A. Pound Identification Lab, Cancer/Genetics Research Center, 2033 Mowry Road, Gainesville, FL 32610*

After attending this presentation, attendees will appreciate the presence of subjectivity in forensic anthropology and understand how to constrain this subjectivity by acknowledging sources of bias, developing new research and technologies, and engaging in both intra-disciplinary and inter-disciplinary communication and theory-building.

This presentation will impact the forensic science community by discussing the implications of presenting forensic anthropological science as purely objective and by suggesting realistic ways to constrain scientific subjectivity with data, theory, and technologies that are continuously advancing.

The field of forensic anthropology faces a future of increasing standardization and quantification of error. This presentation proposes that forensic anthropologists cannot continue to present their data as unbiased and purely objective. Like any social science, forensic anthropology is colored by subjectivity — but social science is not necessarily bad science. By evaluating their biases, learning from each other and from other disciplines, and continuously updating and constraining their interpretations of data, forensic anthropologists can achieve a level of mitigated objectivity that more accurately reflects the capabilities of their science, while still presenting accurate and precise data.

In the wake of the post-positivist theoretical turn in archaeology and the theoretical swing toward relativism in cultural anthropology, much of the field of forensic anthropology still maintains the positivist ideal of objective, value-free science. This may be due to the frequent status of forensic anthropologists as expert witnesses, and their desire to portray results as accurate, precise, replicable, and statistically (and legally) defensible. In the post-*Daubert* era, the forensic sciences have been increasingly scrutinized for their standardization and objectivity, and the questions increasingly arise: Is forensic anthropology *scientific* enough? Can it be “science with a capital S”?

Though an unbiased, purely objective forensic anthropological science is an understandable goal, it is difficult, if not impossible, to realize. Science is itself a social process and it is constantly changing. Scientific models necessarily reduce heterogeneity to homogeneity and the values of scientists affect both the re-presentations they create and their subsequent interpretations of them. But in spite of its social nature and inherent reductionism, science works: through sound scientific practice, anthropologists accumulate knowledge that constrains their constructions and interpretations.

While forensic anthropology may not be capable of achieving pure objectivity, anthropologists can aspire to a mitigated objectivity. The key is not purging data of their theory-laden nature, but rather foregrounding and explicitly scrutinizing any external values with which they are infused and committing to evaluating, emending, and updating those data continuously as technologies advance and as theories and interpretations develop and change. The more thoroughly anthropologists understand the types of actors/agents that affect what they observe and present as “objective,” the more accurately they can acknowledge and quantify potential sources of error and bias. Every American Academy of Forensic Sciences (AAFS) meeting represents a step in this direction, showcasing the application of new technologies with the capacity to reduce error, the refinement of methods that better constrain scientific interpretations, and perhaps most importantly, the inclusion of new perspectives in the Anthropology Section with the potential to enrich forensic anthropological practice with cultural and archaeological theory and method.

In this presentation, forensic anthropological casework will be used as a framework for illustrating the process of constraining subjectivity in anthropological science. From recovery through analysis, anthropologists must interpret what they see in the ground and in the laboratory, creating reports, maps, and other documentary re-presentations that are value-laden and necessarily reductionist — presenting certain theories, features, and perspectives while backgrounding others; however, cultural theory enhances the interpretation of context, geological and taphonomic theory constrains these interpretations, and evolutionary theory guides conclusions drawn about the remains.

In their pursuit of sound science — evaluating their own subjective biases, constraining their interpretations with theory, and espousing a sense of mitigated objectivity — forensic anthropologists must commit to a continuous process of constraint, a process which involves learning not only from each other, but also from the other subdisciplines of anthropology and the other disciplines of forensic science.

Anthropological Theory, Subjectivity/Objectivity, Error/Bias

Anthropology Section - 2015

A112 Context and Cognitive Bias: Informed Applied Science vs. Working in the Blind

Michael W. Warren, PhD*, C.A. Pound Human ID Laboratory, Cancer & Genetics Research Complex, 2033 Mowry Road, Rm G-17, Gainesville, FL 32610

After attending this presentation, attendees will join a conversation about the differences between applied science and research science. Practitioners subject themselves to cognitive bias by knowing the context in which an investigation is being conducted or does an informed investigation lead to a more thorough and efficient outcome?

This presentation will impact the forensic science community by opening a dialog between researchers and applied scientists related to how forensic investigations are conducted, if and when practitioners should be provided a priori knowledge of a case, and how that knowledge helps or hinders the field of forensic anthropology.

In 1988, human remains were found that were misidentified as being those of a biological female, when in fact, the remains were those of a male-to-female who had undergone treatment for gender dysphoria (e.g., transsexual surgery and hormonal treatment). The theoretical aspects of this case revolve around a discussions related to “blind analysis” vs. “analysis with context.” In this case, the previous forensic anthropologist knew that law enforcement was looking for a “robust” female. Female gendered clothing was found at the scene as well as two silicone breast implants. To further complicate matters, the remains displayed marked pits of parturition. In 1988, the anthropologist was reliant on the current literature of the day, which attributed dorsal pitting and preauricular sulci as being secondary to birth trauma and, therefore, found only in females. So, did the consulting anthropologist misidentify the sex of the decedent because he harbored a cognitive bias due to a priori knowledge of a putative decedent or was he a victim of the current state of the science?

This presentation will discuss the effects of treatment of gender dysphoria on the skeleton. The case will serve as the backdrop for discussing the question, “Should forensic anthropologists always work in the blind or should they integrate contextual clues into their analyses and conclusions?” Cultural anthropologists consider social context and history in their interpretations of behavior; archaeologists must necessarily be provided some context for their site or else they would not be digging there and, to them, context is critical in terms of interpreting the meaning and significance of the artifacts. What about forensic anthropologists? Do they provide a better service to consulting pathologists, law enforcement agencies, and attorneys when provided with the context surrounding the case, or does that information unduly affect their interpretations? For example, when a pathologist provides a forensic anthropologist with the clinical radiographs of a putative decedent, are the results skewed because of some expectation that a radiographic match will be found? When weather data is received for the area in which a body is found, does that alter the estimation of time since death or facilitate it?

It will be argued that research in biological anthropology must be hypothesis driven and “blind” as to the interactions of variables and performed in a way that does not influence conclusions; however, applied science benefits from knowledge of why specific questions are being asked and focuses efforts on aspects of a case that are most likely to yield results, thus avoiding blind paths that may waste the limited time and resources available to forensic practitioners.

Forensic Anthropology, Cognitive Bias, Theory

A113 From Blumenbach to Howells: The Slow, Painful Emergence of Theory in Forensic Race Estimation

Richard Jantz, PhD, University of Tennessee, Dept of Anthropology, Knoxville, TN 37996-0720; Stephen D. Ousley, PhD, Dept of Applied Forensic Sciences, Dept of Anthropology, 501 E 38th Street, Erie, PA 16546; and Joseph T. Hefner, PhD, Michigan State University, Dept of Anthropology, 355 Baker Hall, East Lansing, MI 48824*

After attending this presentation, attendees will have a greater appreciation of how a very simple overarching theory of human differences greatly influenced the earlier forensic assessment of race, both in application and research, and that more recent research has provided empirical data to better understand human variation and its relationship to self-identity and ethnicity.

This presentation will impact the forensic science community by reminding us that forensic research and work are influenced by practical goals as well as prevailing theories and technologies.

Forensic anthropology, an applied anthropology, has for the most part been more practical than theoretical, favoring techniques that apparently help identify remains rather than techniques derived from theory, until the lack of theory made application untenable. Early approaches to assessing the ancestry or race of human remains in American forensic anthropology largely followed typological theories of human variation involving discrete races, namely, that there were three to five categories of people in the world (involving the “Mongoloid,” “Caucasoid,” and “Negroid” races, types, or stocks). This view reflected the thinking of the so-called father of anthropology, Johann Friedrich Blumenbach (1752-1840), and the father of taxonomy, Carolus Linnaeus (1707-1778).

The classifications of Blumenbach and Linnaeus, based on observations such as “lazy,” “distrustful,” or “ferocious” dominated physical anthropology despite a lack of scientific testing. Human races were biological, phylogenetic, and tautological. As Caspari noted, typologists would frequently ignore their own results within the same publication if they contradicted the overarching typological theory.¹ Typological views likely dominated American forensic anthropology because the biological taxonomy for mankind corresponded so well with the “folk taxonomy” of the United States. Hypothesis testing involving typology was not deemed necessary. In 1990, Alice Brues emphasized the main goal and practical nature of forensic anthropology by stating, “We need not emphasize any single technique because of its theoretical attractiveness: that may be done when we want to ‘advance the science,’ not when we merely want to know who it was that was dug up in the back forty.”² In the same publication, Brues lauded Hooton for collecting data on non-metric trait expression from many skeletons from around the world. The problem is, no one, including Hooton, bothered to analyze those data beyond a few short descriptive publications. Finnegan published analyses of cranial and postcranial non-metric traits from different populations in 1972 and 1978, but no one followed up on them. Statistics and sampling theory were absent in most publications, including one by Rhine in 1990 in which the sample size of “Negroids” was three.³ Gill invented a metric method for ancestry estimation between American Indians and Whites using facial indices that was fundamentally flawed for several reasons.^{4,5} With the blind acceptance of typology and the aversion to data analysis, ancestry analysis in forensic anthropology was much more “faith based” than theoretical and scientific.

The epitome of the faith-based approach is found in the trait list approach, seen in publications by Rhine and Gill.^{3,6,7} The trait list approach illustrates the problem of confirmation bias because if “typical” traits are provided, and the ancestry of a cranium is known, one can always find some traits that are present, seemingly providing validation. The trait list approach was insidious because it was easy to apparently validate, to teach, and to learn. The inevitable individuals with traits from different races were poorly dealt with because estimating ancestry was considered an art. Subsequent presentations and publications often explained an observed mixture of typical traits as due to racial admixture.

Rather than collecting trait frequencies from groups, non-metric trait variation was simplified to the point that the trait became the race: a post-bregmatic depression meant Negroid, Carabelli’s cusp meant Caucasoid. When Hefner observed traits with large enough sample sizes, and basic frequencies were calculated, the vacuous nature of the trait list and the trait-as-ancestry approaches became quite clear.⁸

Anthropology Section - 2015

More recently, forensic anthropology, always practically oriented, has become more data- and theory-oriented, especially after the establishment of the Forensic Data Bank (FDB) at the University of Tennessee (UT) and the Daubert decision. Sauer pointed out that social races are what forensic anthropologists must work with and made a testable statement that skeletal morphology is associated with American White and Black social races, a statement that was recently validated using the FDB and explained by institutional racism and positive assortative mating.⁹⁻¹¹ Variation within classical races is now much more appreciated, as is variation over time. Forensic data now provide the basis for further theory building and research into human variation and the association of self-identity and ethnicity with morphological features, genetic markers, and Quantitative Trait Loci (QTLs).

Ancestry Estimation, Scientific Method, Validity

Anthropology Section - 2015

A114 Forensic Applications of Isotope Landscapes (“Isoscapes”): A Tool for Predicting Region-of-Origin in Forensic Anthropology Cases

Lesley A. Chesson, MS, IsoForensics, Inc, 421 Wakara Way, Ste 100, Salt Lake City, UT 84108; Brett J. Tipple, PhD, IsoForensics, Inc, 210 Wakara Way, Ste 100, Salt Lake City, UT 84108; James Ehleringer, 423 Wakara Way, Ste 205, Salt Lake City, UT 84108; and Eric J. Bartelink, PhD, California State University, Chico, Dept of Anthropology, Butte 311, 400 W First Street, Chico, CA 95929-0400*

After attending this presentation, attendees will gain an understanding of the value of isoscapes for predicting region-of-origin in unidentified decedent cases.

This presentation will impact the forensic science community by highlighting applications of stable isotope forensics to issues of human identification.

The goal of this presentation is to describe a theoretical framework for applying stable isotope analyses in forensic investigations, focusing specifically on the use of isotope landscapes — or “isoscapes” — to determine the source of biological materials, such as human remains. This presentation will describe some fundamental stable isotope relationships and demonstrate with case studies the application of isoscapes.

Stable isotope analyses have been used for decades in research settings, but their use in forensic settings is relatively new. The effectiveness of the analytical method is predicated on the ability to precisely measure differences in the ratios of isotopes within a material. Analyses of stable isotope ratios are particularly effective for relating or distinguishing between two samples that have the exact same chemical composition, but unique isotopic compositions.

Often more beneficial than direct sample comparison is origin prediction using measured stable isotope ratios. In this application, the intrinsic chemistry of a material is used to understand its derivation and history. For the identification of an unknown decedent, stable isotopes can provide answers to two questions: (1) are the remains consistent with a known location; and, (2) what are the possible locations from which the remains could or could not have originated?

Origin prediction is possible due to the theoretical relationships affecting isotope ratios in the environment. As an example, physiochemical processes like the evaporation, transport, and condensation impact the abundances of stable isotopes in water molecules and materials derived from water (e.g., plant and animal tissues) in a systematic manner. It is possible to describe isotope ratio variations caused by the spatial patterns of these processes, leading to the development of predictive isoscapes for geolocation purposes. The application of isoscapes can be a powerful tool for investigating unidentified decedents, as demonstrated in two case examples.

First is the case of Saltair Sally, a set of human remains found by the Great Salt Lake, UT, in 2000. Hydrogen and oxygen stable isotope analyses of her hair revealed Saltair Sally was a frequent traveler in the two years before her death, moving between discrete regions of the western United States. The unknown decedent was identified in 2012 and the origin information predicted from the stable isotope measurements fit the (now known) travel-movement history of the individual.

Second is a case from Siskiyou County, CA, where an isolated mandible was recovered from the North Coast Range in 2012. Morphological and metric assessments suggested the decedent was an adult male, although classification of ancestry was indeterminate. Bone and a molar tooth were extracted for carbon, nitrogen, and oxygen isotope analyses; strontium isotope analysis was also conducted on the molar. Regions-of-origin predicted for the bone and molar were compared to determine if the decedent spent his adulthood before death and childhood in similar locations.

Looking forward, the theoretical framework for applying stable isotope analyses and isoscapes demonstrated in this presentation for human remains can be expanded to include other elements, such as lead, and other materials of interest, such as drugs, foods, and spoils of the illegal wildlife trade. As a consequence, applications of isoscapes are likely to grow in the future and play a greater role in both forensic examinations and criminal prosecution.

Stable Isotope Analysis, Isoscapes, Forensic Anthropology

A115 The Anatomy of Age Estimation

Natalie R. Shirley, PhD*, Lincoln Memorial University, DeBusk College Osteopathic Med, 6965 Cumberland Gap Parkway, Harrogate, TN 37752; and Beatrix Dudzik, MA, 3909 Briargate Avenue, Knoxville, TN 37919

After attending this presentation, attendees will better understand the theoretical foundations for making inferences about biological age from skeletal characteristics. This presentation will discuss skeletal age estimation in terms of method development, theory, history, and practice.

This presentation will impact the forensic science community by delineating the role of high-level, middle-range, and low-level theory in skeletal age estimation and by discussing criteria for method development that satisfies the scientific rigor required by the medicolegal community and, ultimately, the ethical demands of the criminal justice system.

Evolutionary theory provides the overarching framework for forensic anthropology and serves as the basis by which we understand and interpret human biological variation, largely on a population level.^{1,2} Forensic anthropologists apply these interpretations to the individual level, requiring the use of middle-range and low-level theories to make the inferences required by forensic casework.¹ Forensic anthropologists use middle-range theory to draw inferences about lifestyle and behavior from the human skeleton, much like archaeologists draw inferences about behavior from structures and artifacts in the archaeological record. The task of developing a biological profile from skeletal remains relies heavily on middle-range theory, whereas low-level theory forms the basis of method development in forensic anthropology. Researchers develop hypotheses from inductive data, test these hypotheses, then evaluate results to determine if predictions are supported or falsified.¹ Experienced skeletal biologists recognize morphological patterns and deduce how these patterns may be related to the aging process, then use these data for method development.

Historically, this form of inductive reasoning provided the basis to develop the earliest published age-estimation methods. These methods were based on observations made by anatomists, including researchers now considered to be the founding fathers of skeletal age estimation. For example, T. Wingate Todd was an anatomist who used his extensive observations and knowledge of anatomical variation to describe macroscopic features associated with age-related changes in the pubic symphysis and cranium. Although his methods have been revised, Todd's observations still form the basis for age estimation from these skeletal indicators. Todd applied low-level theory to investigate age-related changes in the human skeleton and to develop age-estimation standards still utilized today.

Science is an iterative process. Age-estimation methods constantly evolve with the addition of more complex statistical approaches and new data. A relevant criticism of age-estimation methods is that they lack a sound statistical framework. One such technique involves seriating samples into arbitrary age categories and then describing common morphologies observed in each category. Other methods have lumped observed morphologies into phases and calculated descriptive statistics associated with each phase, ignoring the effect that reference sample age distribution has on age estimates derived from the method. Bayesian statistics have been suggested as a means of overcoming the limitations and bias of so called "age mimicry," but these methods have been slow to be adopted, perhaps on account of computational intensity.

Skeletal age estimation too often is taught and practiced in the absence of theoretical context. Emphasis tends to be placed on application and deriving age estimates for reporting purposes without encouraging burgeoning academics to think about how the methods were developed initially and, perhaps more importantly, under what biological framework they are appropriate. This presentation advocates that practitioners, researchers, students, and educators incorporate theory and history into application. In addition, estimation of the biological profile requires an understanding of how skeletal and soft tissue morphologies of modern humans reflect both current and past microevolutionary processes. Understanding human evolution demands a working knowledge of the development and function of the skeleton and the related soft tissues. Thus, within the context of research, education, and forensic application, this presentation promotes the idea that formal training in anatomy, evolutionary theory, and statistics as well as a working knowledge of history and theory in forensic anthropology, is imperative to move the discipline forward.

A116 Theory and Histological Methods

Christian Crowder, PhD, Armed Forces Medical Examiner System, 115 Purple Heart Drive, Dover AFB, DE 19902; and Victoria M. Dominguez, MA, Ohio State University, Division of Anatomy, 1645 Neil Avenue, Columbus, OH 43210*

After attending this presentation, attendees will be introduced to multiple theories that guide research in bone histology. Attendees will understand the importance of examining the theoretical approaches of mentors and peers in order to guide future research.

This presentation will impact the forensic science community by demonstrating that theory is well integrated within forensic anthropology and by reminding researchers to consider theoretical constructs in order to stimulate growth in this field.

It is believed within the broader discipline of anthropology that forensic anthropology lacks a strong theoretical foundation, a perception fueled by the seeming lack of high-level theory development within the field. Forensic anthropology tends to operate within middle-range and low-range theories, which is likely associated with the current focus on method reliability. Furthermore, the multidisciplinary nature of forensic science lends itself to complex theory development making it difficult to devise a comprehensive, unified theory in forensic anthropology. Regardless, when examining a method's development, one readily uncovers the theory from which it was conceived. This certainly applies when reviewing the development of histological methods.

Histological methods follow the principles of bone physiology, which describe bone structure and morphology as being controlled by intrinsic factors and influenced by extrinsic environmental factors. Changes in bone over an organism's life produce tissue level indicators useful in anthropological analyses (e.g., age estimation, differentiating human from non-human). Some theoretical models exploring the reason for bone resorption and formation are discussed.

Early Theories: Bernard and Roux introduced two concepts of bone adaptation: the idea of physiologic homeostasis and the principle of bone functional adaptation based on the dynamic interaction between bone cells and the mechanical environment.¹ Wolff's Law states that bone's mechanical environment determines its final mass and trabecular architecture. While accepted as the foundation for bone's functional adaptation, this theory was based on a static mathematical relationship.

The Mechanostat: In the 1980s, Frost proposed that a mechanical feedback system (dubbed the mechanostat) controls bone mass.² Strain thresholds or set-points called minimum effective strains activate or depress bone modeling and remodeling. The threshold strain ranges determine if, when, where, and how long biologic activity switches on or off and may be altered by hormones and biochemical agents.

Osteocyte Inhibitor Theory: Studies have shown targeted remodeling occurs at the site of microcracks, indicating a cause-and-effect relationship. Frost's original proposal stated that microcracks disrupt canalicular connections between osteocytes, thus providing stimulus to initiate remodeling. The osteocyte inhibitor theory provides a different model, whereby osteocyte-canalicular systems act to inhibit osteoclastic activity. When the osteocyte network is disrupted, the constraining mechanism is released, stimulating resorption activity.

The Principle of Cellular Accommodation Theory: In 1999, Turner reported that the mechanostat theory did not explain why non-weight bearing bones do not resorb away under disuse remodeling or why regulation differs by skeletal sites.³ The principle of cellular accommodation theory states that bone cells learn from their physical and biological environments and that adjusting to a new environment causes set-points to vary from site to site depending on local strain. The set-point will be high in weight bearing bones and lower in non-weight bearing bones.

These theoretical models provide the framework for anthropological research in bone histology and guide data interpretation. For example, researchers may sample non-load-bearing elements to observe more age-related systemic-based remodeling. Others select load-bearing elements, but evaluate areas believed to experience less biomechanical stress (e.g., anterior femur mid-shaft). Some consider biomechanical adaptation as a contributing factor for age-related remodeling and sample cortical regions regardless of the mechanical axes. Similar considerations apply when comparing histological structures across species. Various researchers propose that high mechanical stress/strain results in different osteon structure, shape, and/or density patterns. Others suggest differences result from variation in bone formation rates regardless of stress/strain relationships.

Forensic anthropologists tend to focus on the specific rather than the general, the empirical rather than the theoretical; however, the argument that forensic anthropology lacks theory is nonsensical. As evidenced, researchers subscribe to different theoretical models regarding the factors governing bone histomorphology. Despite differing views, working absent of theory is untenable and leads to results void of any real meaning or interpretive power. Inferences from results should be applied to make population-level interpretations to bridge empirical data and theory.

A117 Theoretical Foundation of Child Abuse Recognition

Jennifer C. Love, PhD, OCME, 401 E Street, SW, Washington, DC 22024; and Miriam E. Soto Martinez, MA, 2615 Skyview Glenn Court, Houston, TX 77047*

After attending this presentation, attendees will gain an understanding of the theoretical foundation upon which the recognition of skeletal injuries associated with non-accidental injury and how the knowledge of pediatric bone health is built.

This presentation will impact the forensic science community by demonstrating the sound scientific principles behind bone health evaluation and fracture biomechanics in infants and children.

Anthropologists are playing a larger role in the diagnosis of child abuse in the medical examiner setting. They are asked to assess fracture patterns and bone quality in autopsied infants and young children. Anthropologic interpretation in this area is based on the understanding that inexplicable fractures or fractures inconsistent with the traumatic history, when found in children with normal bone health, are highly suspicious for non-accidental injury (i.e., child abuse). This understanding is supported by strong theoretic evidence derived from biomechanical and bone strength studies.

Biomechanical engineers use computer modeling and validation tests based on biofidelic dolls to define impact forces associated with common household accidents, such as an infant rolling off a bed or couch. Meanwhile, bone strength studies are conducted to establish the failure point of bone. Understanding impact forces associated with common household accidents in conjunction with bone strength studies form the theoretical foundation upon which anthropologists build their interpretations. An understanding of normal, daily impact events associated with infancy and childhood enables anthropologists to deduce skeletal injuries that are contrary to those events.

Bone health and strength are dependent on the material composition, structure, and density. Failure of normal bone development or lower-than-expected bone density increases the likelihood of bone fragility, predisposing it to fracture under forces generated by normal handling. Physicists have developed various modalities that enable the evaluation of the physical properties of bone, including quantitative computer tomography; dual-energy X-ray absorptiometry, and quantitative ultrasound. The theoretical foundation of the clinical evaluation of bone strength is based on current research correlating material and physical properties of bone with bone strength.

Forensic anthropologists are able to utilize these theoretical principles to develop and validate methodologies for evaluating infant bone health and strength. The Harris County Institute of Forensic Sciences Anthropology Division is conducting such a study. The Division is prospectively studying skeletal injuries observed during infant autopsy with the goal of identifying injury patterns that are significantly correlated with physical abuse. Furthermore, it is evaluating quantitative ultrasound as a method to measure bone health of infants in the medical examiner setting. All decedents under the age of one year at the time-of-death are included in the study. The physical properties of the bone of each decedent are measured through three modalities: (1) quantitative ultrasound; (2) X-ray attenuation; and, (3) bone histology. Preliminary results show that specific skeletal injuries are strongly correlated with non-accidental injury. Also, speed of sound as measured by quantitative ultrasound appears to vary depending on infant age and health status.

Non-Accidental Injury, Fractures, Bone Health

A118 Thinking Outside the Box: Theory and Innovation in Sharp Trauma Analysis

John A. Williams, PhD, Western Carolina University, Anthropology & Sociology, 101 McKee Hall, Cullowhee, NC 28723*

After attending this presentation, attendees will have an appreciation for how sharp trauma to bone can be analyzed using a novel approach.

This presentation will impact the forensic science community by demonstrating that pattern analysis on bone can be accomplished using Geographic Information Systems (GIS), a tool not normally associated with forensic applications.

In 1910, Locard was the first to recognize the principle of the transfer of evidence. Since then, pattern analysis has become one of the fundamental tenets of criminalistics and, by inclusion, forensic science. In the forensic sciences, tool mark pattern analysis is an inter-discipline crossover. For the criminalist, the emphasis is on the transfer of tool-specific characteristics to inanimate objects. In forensic anthropology, the transfer is to bone.

Sharp trauma involving toothed instruments or tools is a case in point. Teeth create transfer evidence in the form of patterned marks on bone. The fundamental theory behind the analysis of these marks is a simple one. Each class of toothed instrument creates a cut-mark pattern unique, or nearly so, to that class of tool or instrument. Symes took this theoretical base and created the first comprehensive documentation of these transfer patterns. His work formed the foundation of this and other studies of toothed instrument cut marks.

Once tool-specific patterns have been recognized, interpretation and identification of an unknown pattern is a matter of comparison to known patterns. In most situations, the analysis of class-specific cut-mark patterns relies on morphometric characteristics, like kerf thickness and kerf profile. As Symes has demonstrated, this is a highly effective method. Yet there are times when morphometric analysis is hindered, if not rendered useless, by the absence of observable class-specific characteristics. There is one feature of tooth-instrument transfer that is nearly universally present — striations on the cut surface or kerf wall. As a saw or other toothed instrument cuts through bone, the teeth leave behind striations on the cut surface. Despite their visibility, these striations have limited diagnostic power in pattern analysis using traditional morphometric methods.

GIS is a computer-based process designed to visualize patterns. GIS has been described as a means of analyzing and interpreting relationships, patterns, and trends. Anyone who has used consumer mapping “apps” has used GIS. While the intent of GIS is to recognize patterns on large geographic regions, size should not be a limiting factor. Looking for patterns on an area the size of a state and on the kerf wall of a cut bone is simply a matter of scale.

The inspiration to use GIS to examine striation patterns on bone came from two recent studies. Both were novel approaches to the use of GIS and demonstrated the value of using tools that were not designed for their original purpose. In the first, Powell and colleagues utilized GIS to map out fracture patterns on infant porcine skulls.¹ In the second study, Rose and colleagues moved to the microscopic level in GIS patterns of bone microstructure.² Their success in the use of GIS in their respective studies demonstrated the effectiveness of GIS in the recognition and interpretation of patterns other than geographic ones. Based on these prior studies, Williams and Davis successfully explored the use of GIS in recognizing and differentiating striation patterns on the cut surface of bone.³ In this study, striation patterns were viewed as the equivalent of variations in geographic topology. Two different saw classes were compared, each with uniquely different striation patterns. GIS consistently recognized these as distinctly different patterns of transfer evidence. Using traditional morphometric methods, such a distinction would not be possible.

The theory of transfer evidence on cut bone has followed the traditional route of morphometric analysis. Recent studies have demonstrated that “working outside the box” by using technologies that were not originally designed for bone-specific patterns has yielded encouraging positive results. These studies have shown that GIS has promise to become a tool in trauma analysis and not merely an interesting academic exercise.

Theory, Cut Marks, GIS

A119 Non-Linear Systems Theory and Its Application to the Assessment of Postmortem Interval

*Charles C. Boyd, PhD**, Radford University, Dept of Anthropological Science, Radford, VA 24142; *William W. Baden, PhD*, Indiana University-Purdue University Fort Wayne, 2101 E Coliseum Boulevard, Fort Wayne, IN 46805; and *Donna C. Boyd, PhD*, Radford University, Forensic Science Institute, PO Box 6939, Radford, VA 24142

After attending this presentation, attendees will understand the application of non-linear systems theory and computer simulation to interpreting and resolving the complex, multivariate problem of determining Postmortem Interval (PMI).

This presentation will impact the forensic science community by demonstrating the application of a non-Newtonian scientific model — non-linear systems theory — to forensic interpretations involving the interaction of multiple human and non-human variables.

Since Dr. William Bass' establishment of the "Body Farm" in 1981, a plethora of decomposition studies have emerged from this and other decay facilities with a goal of developing a more complete understanding of PMI through experimentation and actualistic study. These studies have identified a multitude of variables affecting PMI. In spite of these studies, no overall development of precise region-specific PMI models has been proposed.

The goal of this presentation is to explore the utility of non-linear systems theory and computer simulation in enhancing forensic anthropologists' ability to define PMI. Non-linear systems refer to environments with multiple variables, the interaction of which can produce more complex and unforeseen results. Non-linear systems theory is focused on how those systems are understood and analyzed. It is an ideal theoretical model to use for assessment of PMI, given the large number of interacting variables.

Historical contingency (i.e., the effects of unique or random events) and the impact of agents (both human and non-human) are given consideration in non-linear systems theory. This is important, since such events and agents may not produce patterned behavior but would still have considerable impact on the creation of the forensic scene and its interpretation.

Non-linear systems theory is quite different from the traditional reductionist scientific paradigm in that it does not isolate variables for testing but instead focuses on the results of their interaction. One important method often used in non-linear systems analysis is computer simulation which can explicate past events through the analysis of the interaction of a number of variables. Such analyses can also examine the temporal sequence of events by revealing the emergent (new and/or unique) properties periodically resulting from variable interaction. By recording environmental variables for forensic cases and experimental settings and using these in simulation studies, region-specific models for PMI can be developed which can delineate the temporal sequence of decomposition. These models may then be applied to the interpretation of new cases. The application of non-linear systems theory can, therefore, stimulate a new understanding of the PMI for forensic anthropologists and improve future interpretation of this complex problem.

To illustrate the application of this theory to PMI interpretation, a pilot study involving 20 stillborn pigs placed in different environments and examined over a period of 50 days during late summer is presented. Variables examined include pig weight, microenvironment (indoor/outdoor), degree of insect infestation, ambient temperature, and rainfall. A decomposition scale designated the degree of decay at different intervals. Non-linear simulation showed that decay rates varied between outdoor and indoor specimens. Outdoor specimens decomposed more rapidly and at a higher rate during the first five days; subsequent to this, outdoor and indoor decay rates stabilized and were comparable. This simulation created a model for decay rates of specimens over time and explained the stages of decay in relation to the variables noted above, with cumulative temperature being the most significant variable. To calculate PMI, decomposition score is matched to a value for cumulative temperature, then compared to available climate data.

Previous researchers have considered forensic anthropology to be non-theoretical or burdened with so many complex variables that it cannot be "scientific" in its interpretations. Non-linear systems theory can mitigate these problems by providing a broader definition of scientific theory and a methodology (simulation) whereby multiple variables can be examined in a systematic manner. It also can provide the theoretical and methodological tools to develop regional models for PMI. Non-linear systems theory holds the promise of honoring Dr. Bass' original research goal of reaching a more informed understanding of postmortem interval.

Non-Linear Systems Theory, Computer Simulation, Postmortem Interval

Anthropology Section - 2015

A120 The Forensic Anthropologist as Broker for Interdisciplinary Taphonomic Theory

Daniel J. Wescott, PhD, Texas State University, Dept of Anthropology, 601 University Drive, San Marcos, TX 78666-4684*

The goal of this presentation is to provide attendees with an understanding of why it is necessary to develop interdisciplinary theory within the forensic sciences to address questions related to the postmortem interval.

This presentation will impact the forensic science community by outlining how an interdisciplinary, rather than a multidisciplinary, approach is necessary to accurately and precisely estimate the postmortem interval, and by describing why forensic anthropology is ideally suited to broker this interdisciplinary research to build unifying theories. This presentation follows the planks for this year's meeting — honoring our mentors, learning from each other, and stimulating our future — by discussing a complex issue shared by many of the forensic science disciplines: estimating the postmortem interval.

Estimating the postmortem interval is an issue shared by numerous disciplines, including anthropology, medicine, entomology, and microbiology among others. The complexity of decomposition is well understood and those involved in this area strive to uncover the underlying similarities and rules governing how carrion is recycled. In the past, each discipline has attempted to understand this complexity using their own methods and theories; however, new models and approaches are needed, and this cannot be accomplished if the various disciplines approach the topic separately. Complex issues that are driven by multiple forces, such as carrion recycling, require an interdisciplinary approach where multiple disciplines cooperate to develop new methods and theories that transcend each discipline to solve a real-world, multifaceted problem. An integration of the knowledge from various fields, combining data, methodologies, perspectives, and concepts is needed to develop a more unified theory of forensic taphonomy that describes, explains, and predicts all the phenomena observed. It is only through interdisciplinary research that the common problem of estimating the postmortem interval will be satisfactorily addressed.

With the establishment of the first outdoor decomposition facility, Dr. William Bass sought to describe, explain, and even predict the processes of human decomposition. He also encouraged multidisciplinary studies. Under such an approach, forensic anthropologists have commonly addressed questions related to gross morphological changes in the soft and hard tissues of a decomposing body. Entomologists, on the other hand, have mainly been concerned with questions related to developmental stages of arthropods present on carrion, and microbiologists have addressed the diversity and quantity of microorganism on decomposing remains. Using a multidisciplinary approach, a great deal has been learned about the numerous phenomena that occur during decomposition, including how to describe and explain them. Even so, to this date, the postmortem interval still cannot be predicted, especially longer lengths, with the accuracy and precision needed in medicolegal death investigations.

Since the early pioneering work by Dr. Bass and others, forensic anthropologists have adopted methods from other fields, such as the use of accumulated degree days instead of calendar days, to help account for some of the regional and even micro-environmental differences in climate that affect the postmortem interval. Nevertheless, after the examination of over 200 decomposing human remains at Texas State University's Forensic Anthropology Research Facility, for example, it is clear that gross morphological changes do not strongly correlate with accumulated degree days in central Texas.¹ The reason for this is that the necrobiome responsible for carrion recycling is highly dependent on a number of abiotic environmental factors. As vertebrates decompose, microorganisms, arthropods, mammalian, and avian scavengers compete and, in some cases, cooperate to obtain nutrients from the valuable and short-lived carrion resource. In addition, these scavengers must persist and thrive under varying environmental conditions that sometimes involve human intrusions. Unlocking the mystery of the ecology of carrion recycling is key to understanding and interpreting the process and rate of the postmortem interval in various geographical and ecological regions and for establishing methods that accurately and precisely estimate the postmortem interval. Accomplishing this is only going to be possible using an interdisciplinary approach.

Forensic anthropology has traditionally borrowed and utilized theory and methodologies from both the natural and social sciences in research and evidence interpretation. As a result, forensic scientists are in a unique position to act as brokers in the development of interdisciplinary methodologies and theories. What better way to stimulate the future and honor the pioneering efforts of Dr. Bass and others in this discipline than by facilitating interdisciplinary theory that allows an accurate description, explanation, and estimation of the postmortem interval?

Forensic Anthropology, Interdisciplinary Theory, Postmortem Interval

Anthropology Section - 2015

A121 **Arrows of Influence: The Return Flow of Theory and Method to the Parent Disciplines of Modern Forensic Anthropology**

*Cheryl A. Johnston, PhD**, Western Carolina Human ID Lab, Dept of Anthropology & Sociology, WCU, 101 McKee Bldg, Cullowhee, NC 28723; and *John F. Schweikart, MA*, 326 Misty Point, Cullowhee, NC 28723

After attending this presentation, attendees will have a better understanding of the relationships between the theoretical and methodological foundations of forensic anthropology and those of disciplines which have influenced forensic anthropology historically.

This presentation will impact the forensic science community by stimulating an examination of the evolving relationships between forensic anthropology and its parent disciplines with regard to low-, middle-, and high-level theory. A dialectic “back flow” or return of information and influence is proposed.

Situations in which dominant cultures come into contact with subordinate cultures produce what has been called “contact shock.” This is the overwhelming cultural influence of the dominant culture upon the subordinate culture which may settle over time into a more balanced exchange. Similarly, as forensic anthropology evolved over the last century, it was heavily influenced by other disciplines and may now be reaching a new era in its development, as a more equitable state of exchange with these disciplines appears to be forthcoming. Exponential change in forensic anthropology has come about in recent decades; the contextual framework, perception, and practice of the field have developed under the influence of theoretical and methodological constructs derived from biological sciences, archaeology, geophysics, criminalistics, and molecular biology, among others. This study considers both current and future aspects of informational, theoretical, and methodological “back flow” from contemporary forensic anthropology to several of the disciplines from which it borrowed and adapted theory or methodology in forming a cohesive, evolving discipline.

It will be argued that, as the discipline develops, theories can be offered back to the original disciplines as a means of addressing old questions in new ways. This can be accomplished by linking current and past behaviors via similarities their signatures leave in the environment. Examples of topics from other disciplines to which forensic anthropology can contribute new understanding include: (1) the interpretation of site formation processes in the archaeological record; (2) the interpretation and understanding of sub-surface geophysical signatures and their formative components; (3) the development of systematic training and evaluation of human remains detection dog search methodologies and their potential utility and limitations for archaeological prospection; (4) socio-cultural insights into aberrant behaviors such as homicide, war crimes, and genocide where participants and witnesses are no longer alive; and, (5) studies of modern human variation and their implications for biological anthropology and bio-archaeology. These areas of “back flow influence” have the potential to significantly contribute to new theoretical and methodological approaches to many disciplines that have been important in the development of forensic anthropology. These areas should be fostered by forensic anthropology practitioners as is appropriate to this holistic and dynamic field.

Theory, Archaeology, Method

A122 Strontium Isotope Ratios of Hair for Human Provenancing

Brett J. Tipple, PhD*, IsoForensics, Inc, 210 Wakara Way, Ste 100, Salt Lake City, UT 84108; Thuan H. Chau, MS, IsoForensics, Inc, 210 Wakara Way, Ste 100, Salt Lake City, UT 84108; Lesley A. Chesson, MS, IsoForensics, Inc, 421 Wakara Way, Ste 100, Salt Lake City, UT 84108; James Ehleringer, 423 Wakara Way, Ste 205, Salt Lake City, UT 84108; Christy J. Mancuso, MS, University of Utah, 257 S 1400, E, Salt Lake City, UT 84112; and Luciano O. Valenzuela, PhD, Laboratorio de Ecología Evolutiva Humana (CONICET), Unidad de Enseñanza Universitaria Quequén, Quequén, Buenos Aires, ARGENTINA

After attending this presentation, attendees will gain an understanding of how the distribution of strontium isotopes in human hair is related to geography and how this information can be used to answer questions regarding human origins and movement. Attendees will gain specific knowledge on how strontium is incorporated into hair, how strontium isotope profiles within hair can be used to reconstruct regions-of-residence and travel movements, and how strontium isotopes can be combined with other isotopes to refine human movement histories.

This presentation will impact the forensic science community by demonstrating that the innate chemical composition of human tissues reflects an individual's origin and travel history.

This presentation focuses on the application of strontium isotope analysis to human hair to aid in the identification of individuals of unknown origin or travel history. Reconstructing the travel-movement history of individuals of unknown origins reveals pertinent information for forensic investigations, spanning from nationwide homeland security issues to investigations of unidentified decedents by local agencies. Analysis of stable isotopes in human scalp hair has shown to be a useful tool for reconstructing the recent geographic-movement histories of individuals because hair proteins (i.e., keratin), and the stable isotopes contained within keratin, are fine-scale recorders of an individual's geographical environment.

As an example, the oxygen (O) isotope values ($\delta^{18}\text{O}$) of human hair keratin can provide travel/geographic origin information and guide criminal investigations. This is due to the well-established relationship between the $\delta^{18}\text{O}$ values of human hair and an individual's drinking water. Since the $\delta^{18}\text{O}$ values of drinking water vary predictably across landscapes, the $\delta^{18}\text{O}$ values of human hair correlate to specific geographic regions. These geographic projections of isotope values across landscapes are termed "isoscapes." While $\delta^{18}\text{O}$ isoscapes provide a valuable tool for describing geographical spaces where an individual may have originated, the estimated geographical regions can be broad. To refine these broad region-of-origin predictions, investigators need a complementary isotopic approach that reflects different geographic information.

Strontium (Sr) isotope ratios ($^{87}\text{Sr}/^{86}\text{Sr}$) of human hair have attracted interest as a complement to $\delta^{18}\text{O}$ values, because geographic variations in $^{87}\text{Sr}/^{86}\text{Sr}$ reflect local geology. While it has been previously established that the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of human hydroxyapatite tissues (e.g., bones and teeth) relate to geography, the application of Sr isotope analysis to keratinous human tissues (e.g., hair and fingernails) had been avoided to date due to low Sr concentrations within these tissues; however, recent analytical advances have made analysis of keratin-based tissues possible, which have proven useful in reconstructing animal geospatial histories. As human hair is structurally similar to non-human keratinous tissues, $^{87}\text{Sr}/^{86}\text{Sr}$ values of human hair should also provide geospatial information.

To understand the linkages between the Sr in keratinous tissues and an individual's geographical environment, human hair and tap waters were collected from 55 cities throughout the contiguous United States; the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios were measured on paired hair-water samples. Paired tap water and hair $^{87}\text{Sr}/^{86}\text{Sr}$ ratios were significantly correlated and displayed a 1:1 relationship, indicating no Sr isotope fractionation between water and hair. These results indicate Sr isotope signals from water are reflected in the isotope ratios of the individual's hair and, in turn, the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of human hair provide geographic information relating to the locality where an individual resides. As O and Sr isotope ratios within human hair are both geographically controlled, but reflect different physical and chemical environmental processes, the paired analyses of both O and Sr isotope ratios would allow for a finer resolution reconstruction of the travel-movement history of an individual than analysis of either O or Sr alone.

Geography, Origin, Movement

A123 Refining Hydrogen and Oxygen Isoscapes for the Identification of Human Remains in Mississippi

Monica M. Warner*, Mississippi State University, Dept of Anthropology, 206 Cobb Institute, Mississippi State, MS 39762; Amber M. Plemons, BS, Mississippi State University, 206 Cobb Institute of Archaeology, Mississippi State, MS 39762; Nicholas P. Herrmann, PhD, Mississippi State University, Cobb Institute of Archaeology, Box AR, Dept of Anthro & Mid East Cultures, Mississippi State, MS 39762; and Kate L. Henderson, MS, Mississippi State University, Dept of Chemistry, 310 President's Circle, Mississippi State, MS 39762

After attending this presentation, attendees will understand the importance of conducting regional refinement of hydrogen ($\delta^2\text{H}$) and oxygen ($\delta^{18}\text{O}$) isoscapes for the United States when assessing the variability in stable isotope signatures of tap water.

This presentation will impact the forensic science community by increasing the accuracy of isotope baseline data for the utility of identifying human residential origin and will provide encouragement to conduct regional studies of $\delta^2\text{H}$ and $\delta^{18}\text{O}$ isoscape refinement on a national level.

Isoscapes are maps created to visualize large-scale geographic distributions of isotopes in environmental systems.¹ Baseline isoscapes are generated from the collection of stable isotope data and modeled for large-scale regions using geo-statistical programs. They provide an additional resource for forensic investigators to determine residential origin when assigning human isotope signatures to geolocation. Isoscapes, although accurate, provide imperfect estimates for certain regions with less isotope coverage. For instance, the United States $\delta^2\text{H}$ and $\delta^{18}\text{O}$ tap water isoscapes have insufficient isotope sample coverage for Mississippi (n=4). This research project refines the $\delta^2\text{H}$ and $\delta^{18}\text{O}$ isoscapes for Mississippi to determine whether increased sampling significantly alters the isotope patterns previously reported for the state.

The $\delta^2\text{H}$ and $\delta^{18}\text{O}$ isoscapes for Mississippi were generated from tap water samples collected across the state (n=58). Sample locations were selected by physiographic region and population density to account for diverse water sources. Tap water samples were collected from public restrooms in March and April 2014 and recorded with a Global Positioning System (GPS) unit. $\delta^2\text{H}$ and $\delta^{18}\text{O}$ was measured using a Thermo™ Finnigan™ Isotope Ratio Mass Spectroscopy (IRMS) coupled with an elemental analyzer, and data was normalized to the Vienna Standard Mean Ocean Water-Standard Light Antarctic Precipitation (VSMOW-SLAP) scale. Isoscapes and spatial analyses were conducted with ArcGIS® 10.2, using precipitation and temperature priors from IsoMAP®. $\delta^2\text{H}$ and $\delta^{18}\text{O}$ data were classified into Jenks natural breaks and interpolated using ordinary Kriging. The isoscape data was calibrated using a linear regression model and incorporated into each isoscape using raster math. These isoscapes were compared to the national tap water isoscapes presented in Bowen et al. to evaluate any spatial refinement.²

$\delta^2\text{H}$ values ranged from -18.4‰ to -33.1‰, and the $\delta^{18}\text{O}$ values ranged from -4.10‰ to -5.70‰. These data coincide with those presented in Bowen et al., with the exception of one $\delta^{18}\text{O}$ sample falling between -3.9‰ and -2.0‰ in the coastal region.² Distinct differences were observed between the $\delta^2\text{H}$ and $\delta^{18}\text{O}$ values in east and west Jackson, which may relate to available city water sources. A gradual enrichment of $\delta^2\text{H}$ and $\delta^{18}\text{O}$ values was observed from the northern state boundary toward the Gulf coast suggesting stronger correlation with hydrology rather than physiographic region. Both isoscapes exhibit non-random spatial autocorrelation. The $\delta^{18}\text{O}$ isoscape had significant clustered spatial autocorrelation (Moran's I=0.3568; Z=2.004; p<0.05) with notable patterns in the Mississippi Delta. Isoscapes for various Rare Earth Elements (REEs) will also be presented, which provide a means to cross-reference isotope data for more accurate residential origin estimates.

Increased tap water sampling on a regional scale is warranted for $\delta^2\text{H}$ and $\delta^{18}\text{O}$ isoscape refinement to improve the utility of isotopes for accessing human residential origin. Sample size should be increased in cities with large populations to consider multiple water sources. When utilizing $\delta^2\text{H}$ and $\delta^{18}\text{O}$ isoscapes in forensic anthropology, $\delta^{18}\text{O}$ may be the more reliable indicator due to the increased spatial refinement results presented here. These results will be tested on skeletal remains from Mississippi in the next phase of research using these new assignment models.

Isoscape, Residential Origin, Spatial Refinement

A124 Finding the Graves of the Missing: A Study of Geo-Anthropological Techniques in Bosnia-Herzegovina

Derek Congram, PhD, 901-35 Charles Street, W, Toronto, ON M4Y 1R6, CANADA; Arthur G. Green, MA, Geography and Earth & Environmental Science, Okanagan College, 1000 KLO Road, Kelowna, BC V1Y 4X8, CANADA; and Hugh H. Tuller, MA, JPAC-CIL, 310 Worchester Avenue, Joint Base Pearl Harbor-Hickam, HI 96853-5530*

After attending this presentation, attendees will learn about new geo-anthropological techniques to define search parameters for persons missing and presumed dead from armed conflict. Attendees will learn why the search for the missing in Bosnia, which has relied on witness testimony, has become unproductive and how to use geographic methods to create refined search parameters and discover new sites.

This presentation will impact the forensic science community by showing how geographic techniques can be used by anthropologists to better plan searches as well as to complement or compensate for other, perhaps less reliable, methods. This presentation will demonstrate how geo-anthropological methods enable the more effective prioritization of search areas, perhaps most importantly, when there are no witnesses available to identify burial sites. Attendees will learn how a nearly exclusive reliance on oral testimony in Bosnia-Herzegovina has led to a recent dramatic decline of grave discoveries and missing person identifications despite the fact that there are over 7,000 people still missing from the war. New methods are needed to find the missing for both humanitarian and medicolegal reasons.

Previous research has shown that the movement of victims from the time and place of detention to their burial site is fairly limited. This study uses burial sites as the unit of analysis, using a sample of 274 confirmed burial sites with positively identified victims in Bosnia-Herzegovina. Although many more body disposal sites have been discovered in Bosnia, there are problems with the reliability of information about, among other things, circumstances of disappearance and death as well as victim and/or perpetrator identity. Location precision is another problem with many recovery sites known to date. This study collected and coded data such as victim and perpetrator ethnic affiliation, civil status (e.g., police, military, civilian), combat front lines, site visibility, and other socio-geographic factors. Geospatial and spatial statistical tests were run to examine changes across time and regions throughout the conflict. Tests conducted included spatially weighted regression and Ripley's k-function cluster analysis.

Results show that a 20km buffer around the place of death captures approximately 90% of the victim disposal sites included in this study. Cluster analysis of graves showed their location was not at all random, indicating that the placement of one burial site influences (attracts) subsequent burials. This was especially true for targeted mass killings of civilians where questions of logistics overwhelmed the ability of killers to dispose of all victims at one time and location. Different tests showed a degree of variability in site locations but also allowed the researchers to identify factors that appear to influence offenders in their selection of body disposal sites.

Using these methods to limit and prioritize search areas, investigators can focus their efforts to find new witnesses who are more likely to have direct knowledge of undiscovered sites. Using geo-anthropological methods to understand mortuary behavior in conflict contexts will also enable investigators to better plan for searches in countries where conflict is still ongoing and too dangerous in which to operate, such as Syria, Iraq, and the Ukraine.

A125 Multi-Temporal Remote Sensing of Mass Graves in Temperate Environments

Emily A. Norton, MSc, Bournemouth University, Talbot Campus, Fern Barrow, Poole, Dorset BH12 5BB, UNITED KINGDOM; Andrew Ford, MSc, Bournemouth University, Faculty of Science and Technology, Fern Barrow, Poole BH12 5BB, UNITED KINGDOM; and Paul Cheetham, MSc, Bournemouth University, Talbot Campus, Poole BH12 5BB, UNITED KINGDOM*

After attending this presentation, attendees will understand how multi-temporal, multi-spectral, fine spatial-resolution satellite imagery and derived vegetation phenological metrics can aid in the location and detection of human mass graves in temperate environments.

This presentation will impact the forensic science community by potentially revolutionizing the way mass graves are detected. If successful, mass graves will be able to be detected efficiently over large areas and independent of physical or political borders. Furthermore, data processing and interpretation can occur remotely without having to deploy forensic teams to the field, thus bypassing major logistical and safety issues.

Mass graves resulting from mass disasters, human rights abuses, and war are worldwide, societal, and humanitarian issues which pose huge geographical issues and challenges to those responsible for their investigation. Existing published scientific literature detailing appropriate techniques is limited and scarce with the methods used often being ad hoc and based on available resources and finances rather than being the most scientifically appropriate.

Recent years have seen mass graves become a stimulant for criminal proceedings and investigations. Consequently, the detection of clandestine mass graves is at the forefront of international forensics and is considered of ever-increasing forensic importance.

This presentation will initially detail results relating to the investigation of phenological differences of a large-scale, proxy, decadal mass grave site resulting from the 2001 foot-and-mouth disease outbreak in the United Kingdom. This provides a pre-operational proof of concept for clandestine human mass grave detection in temperate environments using multi-temporal (18-day repeat period or multiple thereof), multi-spectral (visible and infra-red, .45 to 12.5 μ m), fine spatial resolution (30m ground sample distance) orbital remote sensing. A dense time-series of archive cloud-free Landsat Thematic Mapper (TM) and Enhanced Thematic Mapper Plus (ETM+) satellite imagery (1999-2011) has been used in conjunction with imagery from the Disaster Management Constellation (DMC) imagery (2002-2011) to quantify phenology of the vegetation directly above the grave and the undisturbed vegetation surrounding it.

Results will also be presented which detail the application of the aforementioned imagery and method of the detection of clandestine human mass graves in Bosnia. In this instance, imagery from the early 1990s to the 2000s is used to cover the period of mass grave interment and exhumation resulting from the conflicts in the 1990s. Within-season and inter-annual phenological metrics (for exhumed human mass graves of known location) have been critically evaluated as a means of detection, which can in turn be applied to detection elsewhere.

Mass Grave, Remote Sensing, Phenology

Anthropology Section - 2015

A126 **Twenty-Eight Years of Forensic Anthropological Casework in the Northeastern United States: Trends, Patterns, and Lessons Learned**

Alexandra R. Klales, PhD, Mercyhurst University, Dept of Applied Forensic Sciences, 501 E 38th Street, Erie, PA 16546; Sara M. Fredette, BS, Mercyhurst University, Dept of Applied Forensic Sciences, 501 E 38th Street, Erie, PA 16546; Katie Cline, BS, Mercyhurst University, Dept of Applied Forensic Sciences, 501 E 38th Street, Erie, PA 16546; and Dennis C. Dirkmaat, PhD, Mercyhurst University, Dept of Applied Forensic Sciences, 501 E 38th Street, Erie, PA 16546*

After attending this presentation, attendees will be familiar with forensic casework encountered in the northeastern United States, as the current study is the first long-term analysis of cases in this region.

This presentation will impact the forensic science community by revealing and detailing trends, patterns, and factors that may be encountered in similar regional casework and by providing comparative data for other regionally focused case syntheses.

In the past 20 years, there has been a shift in the field of forensic anthropology from merely a laboratory-based discipline, concerned only with the establishment of a biological profile, to a broad spectrum discipline that also includes forensic archaeology, forensic taphonomy, and trauma analysis.¹ As a result of this expansion in the real and perceived roles of forensic anthropology, forensic anthropologists are being routinely called upon to assist in more cases. Unfortunately, analyses of the trends in casework conducted by forensic anthropologists are rare and are often specific to a particular region of the country; however, these analyses can provide important information about trends in the field that may be used by practitioners and also by educators to re-evaluate the focus and needs of their academic programs as the field shifts and changes. Comprehensive reviews of casework from specific regions can reveal patterns of: (1) taphonomic factors (e.g., types of animal scavenging) to create better Postmortem Interval (PMI) estimates; (2) decedent deposition, including locations and environments; (3) decedent demographics (e.g., sex/age/ancestry differences); and, (3) trauma, all of which can then be used as Komar notes, in the future “to generate research models, support court testimony, and provide comparative data...”²

This presentation focuses on forensic casework from 1986 to 2013, first at the University of Pittsburgh and later from the chair of Mercyhurst University’s Department of Applied Forensic Sciences (DAFS) in Erie, PA. A sample of 543 cases from the DAFS case database were evaluated and information on requesting agencies, specific case location, number/types of cases, depositional environment, recovery season, taphonomic influences, decedent demographics, and skeletal trauma were compiled and analyzed.

Over the period of observation, especially since 1991, caseload steadily increased, which can likely be attributed to: (1) employment of forensic archaeology; (2) education of law enforcement and coroner/medical examiners regarding roles and benefits of forensic anthropology/archaeology; (3) technological advances in timely and accurate evaluations of forensic significance; and, (4) producing high-quality recoveries, analyses, and reports. Cases conducted were documented from 15 states (mostly Pennsylvania, western New York, and eastern Ohio), four countries, and the territory of Guam. Most (79.9%) were modern forensic cases, while others were deemed non-forensically significant upon recovery (historic: 17.0%; prehistoric: 3.9%).

Human cases submitted for laboratory analyses alone were more prevalent (22.1%) than cases involving forensic archaeological recoveries (15.7%) despite the value of visiting the scene and conducting recoveries. Approximately half (42.2%) of the cases were evaluations of forensic significance (human vs. non-human), several of which were consultations for wildlife services and humane societies. Most modern cases involving forensic archaeological recoveries occurred during fall (34.1%) and summer (29.4%). The higher incidence during these months is likely explained by hunting in fall and camping/hiking during summer in remote areas, given that: (1) most of these recoveries occurred in wooded areas (43.7%) or open fields (12.6%); and, (2) surface scatters (50.6%) were more common than burials (32.9%), fatal fires (8.2%), or mass fatalities (8.2%). The remaining case types included searches (10.5%) and reviews of cases (6.8%). In cases with documented trauma, blunt force (28.4%) was most common, followed by ballistic (25.3%), multiple types (18.9%), fire (16.8%), and sharp (4.2%) trauma. In cases with both known and estimated age, adults in their prime (30-55years) were most prevalent. Males and individuals of Caucasian descent were encountered more frequently in both lab analyses and recovery cases. These results correspond with the known demographics of Pennsylvania, given that 83.5% of the population is “White” and that males (48.8%) and females (51.2%) are nearly evenly represented.³

The current research uses the aforementioned data and results as a basis for further interpretations of regional trends in the field, to evaluate how the discipline is progressing, and for future research (e.g., Dirkmaat et al.).⁴

Forensic Anthropology, Forensic Archaeology, Forensic Casework

A127 Building Sustainable Programs of Recovery and Identification of Human Remains — A Comparative Analysis of Forensic Programs: The Examples of Kosovo and Cyprus

Maria Mikellide, MA, International Committee of the Red Cross (ICRC), 19 Avenue de la Paix, 1202 Geneva, Geneva, SWITZERLAND*

After attending this presentation, attendees will gain a better understanding of the significance of local forensic capacity building in establishing successful programs of recovery and identification of human remains, as learned by the International Committee of the Red Cross (ICRC).

This presentation will impact the forensic science community as well as those involved in the humanitarian domain by drawing on lessons learned from past and existing forensic programs in order to identify the key elements that contribute to their development.

While acknowledging that success cannot be easily defined or quantified — especially in a context where a plethora of specialists and non-specialists are called to contribute to the process while an even greater number eagerly and apprehensively await for results — the goal of this study is to identify the markers of success as well as the context-specific adversities and socio-economic and socio-political parameters that define the trajectories of forensic programs.

For the purposes of this study, success will be assessed on the basis of: (1) operational continuity; (2) quality of forensic work by adhering to best professional standards; and, (3) activities performed (percentage of persons exhumed and identified).

The presentation will begin with a short historical overview of forensic activities from the 1980s to the present day, providing background from South America, the Balkans, the Middle East, and Asia before turning its focus to the specific examples of Kosovo and Cyprus.

The two European examples were selected based on similarities in context, including the scale and the demographics of the missing population. The island of Cyprus, with a population of 600,000 in 1960, experienced two periods of inter-communal armed conflict, during which approximately 2,000 individuals went missing; in Kosovo — with a population of two million — approximately 6,000 individuals went missing during the armed conflict that broke out in 1998, following the break-up of the former Yugoslavia.

By comparing the two contexts, where the scale is similar yet the approach is completely divergent — Kosovo as an immediate response program with shorter-term legal objectives and Cyprus as a longer-term program with humanitarian objectives — the goal of this study is to extrapolate and consolidate the factors at play and, through statistical analyses and comparison with other contexts, scientifically corroborate the hypothesis that building local capacity is key to success.

In order to achieve the above, the variables that will be looked at include: (1) the nature of the conflict (armed conflict/enforced disappearances); (2) political will; (3) availability of funding; (4) nature of the mandate (legal/humanitarian); (5) involvement of international agencies (external forensic personnel); (6) socio-economic circumstances; (7) staff turnover; and, (8) training and involvement of local forensic practitioners.

Although it has been the long-held rhetoric among forensic experts, international aid agencies, and other stakeholders that investing in local capacity is key to sustainability, there remains a significant gap in the scientific literature — especially for the two contexts upon which this presentation focuses — to scientifically support the argument and to document the long-term practical implications of the (non)involvement of local practitioners and the overreliance on external help. Through both quantitative and qualitative analyses, this study seeks to address this gap, contribute to the historical documentation of the evolution of forensic programs, and provide recommendations for the establishment of future ones.

Data for this study have been collected from ICRC archives, scientific articles and book chapters, websites of international agencies, as well as through interviews with the forensic and non-forensic personnel who provided invaluable and previously unpublished material.

With the on-going conflict in a great part of the world today and 30 years since the application of forensic principles to human rights investigations in Argentina, which saw Clyde Snow's commitment and vision to train a group of local young students, this presentation hopes to build on the collective experience of the forensic community, empower a new generation of forensic scientists, and encourage international organizations to ensure that local authorities assume greater responsibility and local ownership.

Humanitarian Forensics, Forensic Capacity Building, Forensic Strategies

A128 The Impact of Daubert on the Admissibility of Forensic Anthropology Expert Testimony

Kate M. Lesciotto, JD*, 117 Moorehead Street, Erie, PA 16508

After attending this presentation, attendees will understand how forensic anthropological expert testimony has been utilized in both federal and state courts as well as how such testimony has fared in admissibility determinations, both before and after the United States Supreme Court's 1993 *Daubert v. Merrell Dow Pharmaceuticals, Inc.* decision.

This presentation will impact the forensic science community by providing information on the range of topics about which forensic anthropologists are asked to testify and how this testimony is currently being evaluated by judges when the admissibility of the testimony is questioned.

During the 1970s, only a single published judicial opinion made reference to forensic anthropological expert testimony. Since then, there has been a steady and significant increase in the discussion of forensic anthropological testimony in judicial opinions, with nearly 250 references between 2000 and 2014. During this surge in testimony, expert witnesses also faced a change in the standard for the admissibility of their testimony. The 1993 Supreme Court *Daubert* decision shifted the question of admissibility from a relatively low threshold of "general acceptance" to a higher threshold requiring intensive evaluation of the expert's qualifications and the relevance and reliability of their testimony.

The goal of this study is to provide an initial analysis of judicial opinions citing forensic anthropological testimony and determine: (1) the individual identified as the forensic anthropologist; (2) whether this individual was certified by the American Board of Forensic Anthropology; (3) the areas in which this individual provided opinion evidence or testimony; (3) whether any challenges to the admissibility of the testimony were raised; and, (4) if there were any challenges, whether the testimony was admitted or excluded. A comparison of the challenges occurring before *Daubert* to those after *Daubert* provides an indication of whether *Daubert* has actually had a significant effect on forensic anthropological expert testimony. Searches were conducted using two legal databases, encompassing written judicial opinions from all federal and state courts. These databases were searched for the phrases "forensic anthropology" and "forensic anthropologist." Three hundred and thirty-three unique cases were identified and analyzed.

By topic, the most common area of testimony is trauma and/or tool mark analysis (40% of judicial references), followed by biological profile or victim identification (19%), postmortem interval (11%), and a combination of forensic recovery, decompositional processes, movement of remains, footprint analysis, and photographic comparisons accounting for the remaining testimony.

Thirty cases were identified that addressed the admissibility of forensic anthropological expert testimony, including 14 cases prior to *Daubert* and 16 after *Daubert*. Examination of these cases indicates that post-*Daubert* cases do not result in more exclusions. Prior to the *Daubert* decision, in only three cases was forensic anthropological expert testimony excluded, and only a single instance of exclusion was found among the post-*Daubert* cases. Both footprint analysis and photographic comparisons were subjected to a disproportionately higher number of challenges, given the overall low number of judicial references to such testimony.

This study found that *Daubert* does not appear to have actually impacted the outcome of admissibility determinations in the predicted manner. Although many judges cite *Daubert* and follow its framework for analysis of the admissibility of expert testimony, there is no evidence of an increasing number of exclusions of expert testimony in the forensic anthropological context.

Forensic Anthropology, Daubert, Expert Testimony

A129 Getting the Record Straight: Forensic Evidence of the Lurigancho Prison Massacre in 1986

Jose P. Baraybar, MSc, EPAF, Av Mello Franco, #341, Jesus Maria, Lima 11, PERU; Franco Mora, BA, Peruvian Forensic Anthropology Team, Rodolfo Rutte 670-3, Lima 17, PERU; Valeska Martinez, BA, Peruvian Forensic Anthropology Team, Rodolfo Rutte 670-3, Lima 17, PERU; and Oscar Loyola, BA, Peruvian Forensic Anthropology Team, Rodolfo Rutte 670-3, Lima 17, PERU*

After attending this presentation, attendees will have a better understanding of the injuries related to cruel, inhuman, and degrading treatment in a prison context as well as of the complexities of death while in custody.

This presentation will impact the forensic scientific community by showing the way in which inmates, after surrendering, were the subject of numerous episodes of trauma that resulted in their deaths while in custody of the Armed Forces.

According to the final report of the Truth and Reconciliation Commission, in the early morning of June 18, 1986, terrorism inmates secluded in three prisons launched a simultaneous mutiny, in some cases taking prison guards and police hostage.¹ Coincidentally, the XVII Congress of the International Socialist was taking place in Lima, Peru. Then-president Alan Garcia Perez entrusted reestablishing order to the Joint Chiefs of Staff, who in turn assigned one prison to each branch of the military (Army, Navy, and Air Force). The next day, June 19, 1986 the human cost of ending the riots was known: at the prison-island of El Fronton, 118 prisoners and four marines died; at the women's penitentiary, one inmate died; and, at Lurigancho prison, once inmates surrendered, 123 of them were summarily executed in the prison yard.

This study presents the results of the examination of 114 bodies corresponding to adult males between 20 and 50 years of age, who were buried secretly and without identity in various cemeteries in and around Lima by the military immediately after taking control of the prison. Under a Supreme Court ruling, graves were located and bodies exhumed in order to identify them and determine the circumstances in which these individuals died.

While official accounts indicate prisoners were shot to death after being extracted from the pavilion in which they were housed, forensic evidence suggests further episodes of trauma prior to the time of death, including, but not limited to, blunt force trauma to the chest, possibly caused by kicks, stomping, or other mechanisms of compression.¹ Additionally, multiple gunshot wounds from high-velocity missiles, the majority of which were located in the head/neck, chest, and upper and lower limbs, were recorded. Considering the good preservation of the skeletal remains and associated artifacts, it has been possible to associate trauma episodes between bone and clothing.

This case study is a unique opportunity to establish the relationship between the "control of fact," by which an organization (the Armed Forces, in this case) controlled a situation through its command structure, functioning, and hierarchy, and the nature of the injuries sustained by the individuals during the time they spent in the organization's custody.

A130 Need a New Headspace? A Semi-Automated Volumetric Approach for Subadult Age Estimation Using the Spheno-Occipital Sychondrosis

Nicolene Lottering, BS*, Queensland University of Technology, School of Biomed Sci, Faculty of Health, 2 George Street, Gardens Point, Brisbane, Queensland 4001, AUSTRALIA; Mark D. Barry, MS, Queensland University of Technology, High Performance Computing and Research Services, 2 George Street, Brisbane, Queensland 4001, AUSTRALIA; Donna M. MacGregor, MSc, Queensland University of Technology, School of Biomedical Sciences, Faculty of Health, Gardens Point Campus, Brisbane, Queensland 4001, AUSTRALIA; Clair L. Alston, PhD, The Queensland University of Technology, School of Mathematical Sciences, 2 George Street, Brisbane 4001, AUSTRALIA; and Laura S. Gregory, PhD, Queensland University of Technology, School of Biomedical Sciences, Gardens Point Campus, Brisbane, Queensland 4001, AUSTRALIA

After attending this presentation, attendees will appreciate the advantages and principal processes of applying a semi-automated growth plate measurement protocol based on voxelization and volume calculation to quantify the tissue composition of irregular skeletal regions such as the spheno-occipital sychondrosis.

This presentation will impact the forensic science community by providing an attractive alternative to traditional phase-based age-estimation methods by introducing quantitative methodologies to measure material density distributions embedded in cross-sectional tomography data.

Due to the high probability of recovering the skull in anthropological casework, the spheno-occipital sychondrosis is frequently used as an indicator of subadult age, as it constitutes the last site in the cranium to terminate growth. Disparity regarding the reported age of complete sychondrosis fusion is evident in current literature, possibly attributed to inconsistencies in research design and visualization medium. Consequently, the reliability of ordered age-phase strategies employed in qualitative assessment may be questioned due to: (1) ambiguity in phase descriptions; (2) variation in the number of stages; and, (3) significant overlap in age ranges between consecutive phases.

Volumetric analysis using automated segmentation algorithms constitutes standard practice in medical science for monitoring skeletal toxicity and neurological assessment of intracranial pathologies, where voxelization and volume calculation are imperative for diagnostic and treatment decisions. A semi-automated method for volumetric measurement was developed based on differential voxel intensity values of the Hounsfield scale (HU) that discriminate material composition of the spheno-occipital sychondrosis in Computed Tomography (CT) orthoslices. Manual segmentation was conducted to: (1) create a sub-volume of the original Digital Imaging and Communications in Medicine (DICOM) stack; and, (2) isolate the joint space to create a binary tissue classification mask. MATLAB® commands were written to eliminate voxels exceeding the mask and to produce a histogram of intensity values for each individual based on voxel-clustering of biological material. Intensity values were correlated to specific tissue types (i.e., hyaline vs. calcified cartilage) using Bayesian probabilistic analysis, followed by tissue volume calculations using the voxel count and size. Linear sychondrosal measurements were conducted to eliminate the effect of size. The protocol was applied to cranial CT data from The Skeletal Biology and Forensic Anthropology Research Osteological Database on 169 Australian individuals aged birth to 18 years to generate preliminary density histograms for age estimation using mixture modeling.¹ Cumulative Density Functions (CDF) for key age ranges were calculated using a sub-sample of this data, with age estimates of remaining individuals based on agreement with the conceptualized CDFs using the Kolmogorov-Smirnov test. Non-linear regression with variance modeling was utilized to formulate predictive algorithms, which will be subject to validation on an independent sample acquired from The Royal Children's Hospital, Brisbane and disclosed in February 2015.

Preliminary results demonstrate a gradual decline in standardized cartilaginous volume of the spheno-occipital sychondrosis until 16.3 and 13.8 years in males and females, respectively, which constitutes the age of complete fusion in this population. In the neonate, mean cartilaginous volume in males was $461.67 \pm 49.28 \text{mm}^3$ compared to $299.35 \pm 32.76 \text{mm}^3$ in females; with males exhibiting significantly greater volumes ($P < 0.05$) across all age intervals until 14 years, which correlates with delayed closure of the sychondrosis. Males exhibit a consistent linear decline in volume with age, while the rate of decline accelerates after eight years in females. Height and width variables demonstrate expansion through adolescence, the most prominent increase observed between birth and four years during which time chondrocyte proliferation and matrix production occur rapidly. Proceeding this period, endochondral ossification commences at the superolateral borders, causing a reduction in the gradient of growth. Significantly, voxel cluster distributions successfully discriminate tissue changes with increasing age, with neonates exhibiting a cluster peak corresponding to the density of fibrous tissue. At five years of age, the highest proportion of intensity values denote hyaline cartilage in contrast to cluster peaks at 150-250HU at 14 years

Anthropology Section - 2015

of age, emphasizing significant cartilage calcification prior to complete ossification (+250HU) at 16 years in Queensland males. New mathematical models, validated on a large, modern Australian population, will be introduced as a tool for methodological refinement, providing a robust alternative or adjunct to current subadult aging methods. The utility of the proposed methodological approach to epiphyseal growth plates of the post-cranial skeleton for multi-factorial age estimation will also be discussed.

Subadult Age Estimation, Volumetric Analysis, Spheno-Occipital Synchondrosis

Anthropology Section - 2015

A131 Radiographic Age Estimation of the Knee in Young Children

Maureen Schaefer, PhD*, Michigan State University, Division of Human Anatomy, E Fee Hall, 965 Fee Road, East Lansing, MI 48824-1316; and Lucina Hackman, PhD, WTB/MSI Complex, Dow Street, Dundee, Angus DD1 4AH, UNITED KINGDOM

After attending this presentation, attendees will be offered practical statistics to transform a single skeletal age estimate into a probable chronological age range that is wide enough to reflect the scope of normal variation, yet narrow enough for the estimate to be of value.

This presentation will impact the forensic science community by providing tighter age intervals to assist with radiographic age estimation of young children between the ages of zero to six years. The reported intervals will at the same time be wide enough to reflect normal variation in developmental timings, thus offering a practical resource to forensic practitioners.

One of the more challenging aspects of forensic age estimation is the balance between producing an estimate that is wide enough to cover the full extent of normal human variation, yet narrow enough for the estimate to be of value. While narrow estimates are optimum in theory, an interval that is too small leads to false exclusion of possible ages, which may potentially compromise identification efforts. In an effort to optimize this balance, predicted age ranges often vary in their reported widths depending on the overall life period of the individual. Generally speaking, the younger the individual, the narrower the estimate that can be provided. One of the more useful methods of estimating age in children includes the radiographic atlas technique.¹ This technique considers the morphological changes that epiphyses within a specific joint region undergo from appearance to full maturity, and thus provides a method that has utility throughout the entire juvenile time period. Radiographic atlases have been published for various joint regions; however, these atlases are known for estimating a single skeletal age rather than a range that includes variable rates of developmental timing. Hackman and Black have recently offered a solution to this conundrum for the joint regions of the knee by offering standard deviations documenting variation in developmental timings, then suggesting that two standard deviations can be added and subtracted from an estimated skeletal age to offer an age interval that transforms the method into a robust technique for estimating age.² This provides a single standard deviation for each of the sexes, regardless of the overall maturity level of the juvenile. The standard deviations reported result in an estimate that is nearly four years in width. While there is no doubt that the window of developmental variation is wide-ranging during the teenage years, is it possible that a tighter estimate can be offered for infants and young children? The sample from which the original standard deviations were calculated is extremely limited in individuals younger than seven years, so does not reflect the more cohesive development that occurs during this time period.

This presentation considers the above question by examining rates of development in young American children as assessed through use of Pyle's and Hoerr's radiographic atlas of the knee. Radiographs from 217 children (107 females and 110 males) between the ages of zero to six years were collected via the juvenile radiographic database developed by Mercyhurst University. Standard deviations representing the difference between skeletal age and chronological age were then calculated according to three general time periods, including the first year, second year, and third through sixth year. As expected, variation was observed to decrease with receding maturity, resulting in the creation of significantly narrower ranges when predicting age. Reported standard deviations ranged between 2.7 months and 6.7 months for females and 2.4 months and 8.0 months for males.

A132 Interpersonal Violence in Undocumented Border Crossers From Southern Arizona Between 2006 and 2013

*Cate E. Bird, PhD**, Harris County Institute of Forensic Sciences, 1885 Old Spanish Trail, Houston, TX 77054; and *Angela Soler, PhD*, Joint POW/MIA Accounting Command CIL CONUS Annex, 106 Peacekeeper Drive, Ste 2N3, Offutt AFB, NE 68113

After attending this presentation, attendees will have a better understanding of interpersonal violence in Undocumented Border Crossers (UBCs) who died as a result of homicide in southern Arizona between 2006 and 2013.

This presentation will impact the forensic science community by evaluating peri-mortem trauma, biological variables, and contextual information at an assemblage level in this human rights sample.

While migration across the United States-Mexico border has decreased over the past five years, deaths of UBCs have actually increased. This increase is largely due to the redistribution of migrants along the border resulting from United States immigration control policies, which funnel migrants into less protected, yet more remote and dangerous areas of the border. The Tucson Sector represents one of the most traversed corridors of the border region in the United States. UBCs who die in southern Arizona are examined at the Pima County Office of the Medical Examiner (PCOME) in Tucson, AZ. As such, the PCOME currently handles the greatest number of migrant deaths in the United States.

In order to evaluate patterns of interpersonal violence in UBCs recovered in southern Arizona, biological variables, peri-mortem trauma, and contextual information from crime scenes were collected using investigator reports, autopsy reports, and forensic anthropological examinations. While the majority of UBC deaths between 2006 and 2013 were deemed accidental (42%) or undetermined (48%), approximately 3% represented homicides. In this study, all available homicide cases (n=37) from the PCOME during this period were reviewed, and included both identified and unidentified decedents. The sex and age of decedents were recorded, as were their associated decompositional stage, percentage of body recovered, and degree of trauma. Variables related to peri-mortem trauma were analyzed when possible and included the mechanism of trauma, anatomical location of trauma, and direction of force. Contextual information related to the crime scenes was also evaluated, including recovery site, disposition of the body, recovery cohort, presence of concealment tactics, and material evidence.

Preliminary results indicate that all UBC homicide victims from 2006 to 2013 were male. Decedents' ages were verified and estimated, and ranged from the mid-teens to 57 years at death. Approximately 46% of decedents were classified as young adults (20-35 years), while 38% were middle adults (35-50 years). Approximately half of all decedents exhibited multiple mechanisms of trauma; however, not all mechanisms were related to the cause of death as determined by the pathologist. Gunshot wounds were observed on approximately 84% of decedents, with fewer cases of blunt force trauma (38%), sharp force trauma (5%), and undetermined trauma (19%). Individuals exhibiting projectile trauma were shot between one and four times, with single gunshot wounds (55%) being the most common. Evaluation of contextual information related to the crime scene indicates that the majority of decedents were discovered alone (79%), on the ground surface (81%), and in the open desert (86%) in Pima, Pinal, and Santa Cruz Counties. Attempts to conceal victims' remains by perpetrators were observed in approximately 60% of homicide cases.

Employing a population-based approach, this study reports on patterns of interpersonal violence in hopes of recognizing one of many challenges encountered by this vulnerable population. In general, the majority of UBC deaths in southern Arizona are not violent in nature but rather accidental and related to the harsh environmental conditions of crossing arid and isolated terrain.¹ The low levels of homicidal violence amongst UBCs within the Tucson Sector stand in sharp contrast to reports of large-scale atrocities perpetrated against undocumented migrants traveling through Mexico and Central America.² Evaluation of peri-mortem trauma and the crime scenes from UBC homicides in this study suggests isolated incidents of interpersonal violence against individuals rather than the large-scale, systematic targeting of migrants occurring south of the border. Future research intends to examine the frequency and nature of violence in undocumented migrants from other areas (e.g., northern Arizona, California, and Texas) in order to determine how interpersonal violence varies by border region within the United States.

Interpersonal Violence, Peri-Mortem Trauma, Undocumented Border Crossers

Anthropology Section - 2015

A133 Differentiating Peri-Mortem From Postmortem Blunt Force Trauma by Evaluating Fracture Tension Surface Topography Using Geographic Information Systems

*Kelsea Hentschel, MA**, University of South Florida, Anthropology Dept, 4202 E Fowler Avenue, SOC107, Tampa, FL 33630; and *Daniel J. Wescott, PhD*, Texas State University, Dept of Anthropology, 601 University Drive, San Marcos, TX 78666-4684

The goal of this presentation is to present the results of a novel method that uses Geographic Information Systems (GIS) to quantifiably distinguish between peri-mortem and postmortem blunt force trauma fractures. Attendees will learn that microscopic topographic differences are observable on the fracture tension surface between bones fractured near the time of death and those fractured later in the Postmortem Interval (PMI), and that these differences can be detected and quantified from high-resolution digital images of the fracture surface using GIS software.

This presentation will impact the forensic science community by introducing a new quantifiable method for analyzing the fracture tension surface morphology by using GIS software to differentiate peri-mortem from postmortem blunt force trauma in forensic anthropological investigations.

Forensic anthropologists must be able to accurately distinguish between wet and dry bone fractures in cases involving blunt force trauma. While previous research has established that fracture surface morphology can provide clues to differentiate between peri-mortem (wet) and postmortem (dry) fractures, no studies have made attempts to calibrate or measure these changes.¹⁻⁴ The present study explores the use of GIS to assess and quantify changes in the fracture tension surface topography of bones broken throughout the PMI. Because of its ability to evaluate spatial data, GIS software is well-suited to analyzing spatial patterns in the irregular landscape of a fracture surface.⁵ The goal of this study is to establish if fracture surface topography can be consistently used to differentiate between peri-mortem and postmortem bone fractures. The tension surface of the fracture was chosen for analysis because previous research has found that osteons, when placed under tension, will “pull-out” of the fracture surface and create pits and projections on the fracture surface.⁶ These pits and projects are read by GIS software as hills and valleys on the fracture surface.

A total of 144 fracture surfaces from pig long bones broken near the time of death and at weekly periods throughout the postmortem interval were imaged using a NextEngine® 3D scanner. The scans were trimmed and imported into ArcMap™ 10.1 in vector format as coordinate points. The Hotspot Analysis tool was used to identify statistically significant areas of high elevation (hot spots) and low elevation (cold spots) and assessed whether those clusters were statistically significant within the context of neighboring feature values. For each fracture surface, the percentage of the total tension surface area considered a cold spot (valley), hot spot (hill), and intermediate value (flat area) were calculated.

Analysis of variance results indicate there is a significant difference in topographic features (hot, cold, and intermediate spots) and temporal intervals corresponding to early, middle, and late decomposition ($p=0.011$, 0.026 , and 0.025 , respectively). Regression analysis shows low correlation between months in the PMI and the topographic features. The overall trend in the data suggests that bones broken closer to the time of death have a higher percentage of hot and cold spots compared to bones broken later in the PMI. This implies that the bones broken near the time of death exhibit a rougher fracture tension surface with more pits and projections than bones broken later in the PMI. The microscopic roughened appearance of wet bone fracture surfaces is likely the result of torn collagen bundles and osteonal pullouts; however, as the bone dries, the osteons and collagen become less elastic and more brittle, so osteons and collagen bundles will not stretch under tension. Thus, drying results in a smoother fracture surface. The low correlation between PMI and fracture features suggest that time is not a major causal factor, but rather the change in topography is likely the result of the loss of organic material as the bone dries. The findings of this research demonstrate promise for using GIS in forensic anthropological fracture research and cases and that this method warrants further investigation.

Peri-Mortem, Trauma, Geographic Information Systems

A134 Estimating Skeletal Differences Between Contact and Non-Contact Gunshot Wounds to the Head: The Role of Forensic Anthropologists in Understanding Circumstances of Death

Maria Alexandra Lopez, BA, University of Tennessee, Dept of Anthropology, 250 S Stadium Hall, Knoxville, TN 37996; and Dawnie W. Steadman, PhD, University of Tennessee, Dept of Anthropology, 250 S Stadium Hall, Knoxville, TN 37996*

After attending this presentation, attendees will understand some of the skeletal differences observed between contact and non-contact gunshot wounds to the head and will appreciate the potential of skeletal trauma analysis in understanding circumstances of death.

This presentation impacts the forensic science community by contributing to bone trauma analysis and stressing the role of forensic anthropologists as valuable consultants to forensic pathological determination of cause and manner of death.

The analysis of gunshot trauma in medicolegal contexts is relatively straightforward for medical examiners when soft tissues are well preserved. One of the key factors to guide the estimation of manner of death is range-of-fire; however, in skeletonized remains, the task is more difficult because the analysis lacks soft tissue evidence. This project evaluates the contribution of skeletal injury, particularly fracture patterns, to evaluations of gunshot distance. This study was conducted using a case-based analysis approach to determine the presence or absence of skeletal differences between known contact and non-contact gunshot wounds to the head.

Fifteen contact gunshot cases to the head (12 suicides, one homicide, and two undetermined) and 23 non-contact gunshot cases (all homicides) were collected for a total of 38; ten from the McCormick Collection at The University of Tennessee, four from the Office of the Chief Medical Examiner in Knoxville, TN, three from the Wayne County Medical Examiner's Office in Detroit, MI, and 21 from the Modern Skeletal Collection of the National Institute of Legal Medicine and Forensic Sciences in Bogotá, Colombia.

Information on range-of-fire and type of caliber was provided in the autopsy and ballistic reports. All cases were wounded by low-velocity bullets. A total of 24 variables were collected to characterize the overall injury analysis, including quantitative data, such as entrance and exit diameters, number of radiating and concentric fractures associated with entrance and exit defects, number of secondary fractures, and average length of fractures. Qualitative data include anatomic location of entrance and exit defects and types and location of symmetric fractures. Kruskal-Wallis Non-Parametric test was conducted to find statistically significant differences between contact and non-contact gunshot wounds ($p=0.05$).

Results indicate that, compared to non-contact wounds, contact gunshot wounds are associated with higher frequencies of: (1) entrance fractures; (2) exit fractures; (3) average length of exit fractures; (4) total number of secondary fractures; and, (5) average length of secondary fractures.

Qualitative data results suggest statistically significant differences in the anatomic location of entrance defects. Common entrance locations for suicides are in the mouth, the temples, and the forehead. Non-contact gunshot wounds do not follow any pattern because homicidal wounds occur more randomly with less localization.

Two types of secondary symmetric radiating fractures occurred more frequently than others: (1) bilateral diagonal fractures going through the external acoustic meatus and the squamous portion of the temporal bone; and, (2) bilateral diagonal fractures on the maxilla going from the inferior orbital border to the alveolar process. The first type occurred equally often in contact and non-contact gunshot wounds with no specific entrance defect location associated. The second type appeared to be more frequently associated with contact gunshot wounds with no specific entrance location related. Findings indicate that no specific type of fracture is associated with range-of-fire and or specific entrance locations; however, it is suggested that the analysis of these types of fractures needs additional examination.

The results are based on a small sample and must be carefully considered. Further research is important to establish if these findings are consistent and, hopefully, to estimate the presence or absence of craniofacial fracture patterns associated with contact gunshot wounds to the head. Unfortunately, the number of cases in this study does not support evidence of any frequent type and/or location of fractures in relation to range-of-fire. Additionally, while the establishment of manner of death cannot be solely based on scientific analysis of the victim's remains — due to the significance of an interdisciplinary investigation of each case — the importance of the expertise of forensic anthropologists in the analysis of bone trauma and their contributions in the understanding of circumstances of death is emphasized.

Skeletal Gunshot Trauma, Bilateral Symmetric Fractures, Manner of Death

Anthropology Section - 2015

A135 Identification of Peri-Mortem Cranial Trauma After Cremation: How Easy Is It?

*Federica Collini**, Via Mangiagalli 37, Milan 20133, ITALY; *Francesca Magli*, MA, LABANOF, Dipartimento di Scienze, Biomediche per la Salute, Milan, ITALY; *Alessandra Mazzucchi*, BSc, LABANOF, Dipartimento di Scienze, Biomediche per la Salute, Milan, ITALY; *Emanuela Sguazza*, BSc, LABANOF, Dipartimento di Scienze, Biomediche per la Salute, Milan 20133, ITALY; *Michela Zana*, BSc, LABANOF, Via Luigi Mangiagalli 37, Milano 20133, ITALY; *Alberto Amadasi*, Via Mangiagalli 37, Milano 20133, ITALY; and *Cristina Cattaneo*, PhD, Universta Degli Studi Di Milano, Milan 20133, ITALY

After attending this presentation, attendees will have learned how much of a cranial peri-mortem fracture really survives after cremation and where the pitfalls in distinguishing it from a heat-related fracture may be.

This presentation will impact the forensic science community by demonstrating how traumatic fractures survive cremation, how they may change, and how they may differ from heat-related fractures even after the cremation process through the analysis of 32 cadavers subjected to autopsy, then cremated.

Twenty male and 12 female cadavers between 22 and 90 years of age, were followed and analyzed from the autopsy room to the crematorium. The mean age of the male sample was 58.6 years and of the female sample was 65.9 years. All subject died of head trauma: 30% from traffic accidents; 52% from falls from a height; and, 18% from gunshot injuries. This study focused only on the skull. The advantages of this study were the standardization of all the samples due to the fixed oven temperature and time of cremation (1,200°C for 90 minutes), known demographic (age, sex, weight, and height), clinical information, availability of detailed autopsy reports (injuries and cause of death), and photographs.

Moreover, both during the autopsy and after the cremation, photos of the bone fragments and their edges were accurately taken from different angles with a metric reference. In each case, all fragments were counted both during autopsy (from zero to 25 fragments, with a mean of 6) and after the cremation (from 44 to 106 fragments, with a mean of 78). After a recomposition of the skull fragments according to the bone of origin (parietal, frontal, etc.), the fracture visible at the autopsy, which had been photographed, was searched for among the burned fragments. If the original fracture could not be found, it was classified as “a;” if it could be recognized but had been greatly altered, it was classified as “b;” if it was found to be superimposable in its shape, it was classified as “c.”

Results showed that only 20.8% of peri-mortem fractures were of type “c” (i.e., recognizable and of the same shape); 25% were of type “b;” and 54.2% were classified as “a.” One interesting finding was that if beveling due to the trauma was present during autopsy, it preserved its general shape even after the cremation but was smoother at the edges. As already reported in literature, saw marks were always clearly visible, confirming that the saw action on the bone is demonstrable even after the cremation at extreme temperatures. It also seems that fire-induced fractures generally produce straight, sharp, and acute angles at fracture edges whereas pre-existing traumatic fractures are modeled by fire, creating generally smoother and rounder edges.

In conclusion, this study has shown that in more than half of the cases, the original peri-mortem fracture could no longer be seen. Where the fracture can be detected, in 25% of the cases it is visible but severely altered, and in the remaining cases it is very similar in shape but not superimposable since the margins are rounder and smoother.

Forensic Anthropology, Trauma, Cremation

Anthropology Section - 2015

A136 Computerized Reconstruction of Fragmentary Skeletal Remains

Mohamed Mahfouz, PhD, University of Tennessee, Dept Mechanical, Aerospace, & Biomedical Engineer, 307 Perkins Hall, Knoxville, TN 37996; Emam E. Abdel Fatah, PhD*, University of Tennessee, Dept Mechanical, Aerospace, & Biomedical Engineer, 307 Perkins Hall, Knoxville, TN 37996; Natalie R. Shirley, PhD, Lincoln Memorial University, DeBusk College Osteopathic Med, 6965 Cumberland Gap Parkway, Harrogate, TN 37752; Nicholas P. Herrmann, PhD, Mississippi State University, Cobb Inst Archaeology, Box AR, Dept of Anthro & Mid East Cultures, Mississippi State, MS 39762; and Ali Mustafa, BS, 206 Perkins Hall, Knoxville, TN 37996

After attending this presentation, attendees will have gained an understanding about the process of fragmentary remains reconstruction using computerized methods and the use of Computed Tomography (CT) and 3D models to sort commingled fragmentary remains.

This presentation will impact the forensic science community by sharing results of the developed software program to enable the determination of the number of individuals present and make metric assessments of sex, ancestry, and stature based on statistically sound bone reconstructions.

Within the larger medicolegal system, forensic anthropologists perform the essential task of creating a biological profile to aid law enforcement in identifying unknown human remains — an important first step in the criminal apprehension and conviction process. In cases of mass disasters or commingled remains, the determination of individual biological profile parameters is complicated by the presence of multiple unassociated elements. The ability to make biological profile assessments on isolated bones or bone fragments is critical. Although developed independently, the 3D approach to the quantification of commingled remains is a logical extension of coding and 2D methods developed in zooarchaeology and bioarchaeology.¹⁻³ Recent work quantified small fragmented remains into an Osteological Information System (OIS) using Geographic Information System (GIS) software to derive Minimum Number of Elements (MNE) values and Minimum Number of Individuals (MNI) estimates.³ These systems are time-consuming and are dependent on the observer to manually digitize each fragment into the OIS application. The resulting image provides an MNE estimate for the element under investigation.

Methods: In order to enable the computerized reconstruction of fragmentary remains, a new method was developed to match fragmentary remains with 3D template bones for the pelvis, humerus, femur, and cranium. These template bones are average bones generated from a training set with homologues points on the 3D surfaces. In order to generate such homologues points for all training sets, the 3D models had to be added to a statistical atlas that redistributes the points on the bone surface to ensure correspondence among landmarks.⁴ Fragmentary remains are matched to each template bone using surface descriptors. Outputs of this process are fragmentary pieces that are registered together in space. The next step involves reconstruction of a full bone by interpolating missing data between registered pieces. This step is enabled by optimizing the principal components calculated from the training set. In order to develop and test the system, a highly fragmentary commingled sample was used as a proxy for a mass disaster: the Morton Shell Mound osteological collection. The Morton sample represents over 25,000 human bone fragments from approximately 125 individuals.

Results: During this study, 22,400 bones have been CT scanned — of those 17,700 have been sorted and coded, and 170 bone fragments have been 3D scanned. Using the developed software, the innominate reconstruction had a mean Root Mean Square (RMS) error of 0.6mm with a maximum of 3.29mm error, whereas the skull reconstruction had mean error of 1.1mm. The developed application allows all scanned skeletal remains from each scene to be reviewable within the user interface. An estimate of MNE of the scanned material is provided following osteological protocols developed in forensic anthropology and bioarchaeology.³ Finally, the application calculates a combination of traditional anthropological measurements and frequently used biomedical measurements. The traditional measurements can be used in a program such as FORDISC® 3.0 or manually plugged into equations for the metric assessment of three elements of the biological profile: sex, ancestry, and stature.

This project was funded by the National Institute of Justice (Grant Number 2011-DN-BX-K537).

Fragmentary Remain, Computerized, Commingled

B1 Screening and Confirmation of Nitramine, Nitroaromatic, and Nitrate Ester Explosives in Soil

Harun Sener, MSc, Criminal Polis Dept Istanbul Vatan Caddesi, Fatih, Istanbul, TURKEY; Beril Anilanmert, PhD; and Salih Cengiz, PhD, Istanbul Universitesi, Adli Bilimler Enstitüsü, Cerrahpasa Tıp Fakultesi, Istanbul, 34300, TURKEY*

The goal of this presentation is to inform attendees regarding Liquid Chromatography with Tandem Mass Spectrometry (LC/MS/MS) screening and confirmation methods on explosives.

This presentation will impact the forensic science community by providing attendees with information about a new and original method with low Limit Of Detection (LOD) and Limit Of Quantitation (LOQ) values on explosive determination using LC/MS/MS.

Sensitive, rapid, and inexpensive methods for explosive determination in samples of explosive debris and environmental samples (water, soil, etc.) are important in order to determine the type of explosive substances that are present. In this study, Liquid Chromatography/Atmospheric Pressure Chemical Ionization with Tandem Mass Spectrometry (LC/APCI-MS/MS) was used in order to determine trace amounts of widely used explosives and plasticizers in soil, such as 2,4,6-Trinitrotoluene (TNT), Research Department Explosive (RDX), octogen (HMX), Pentaerythritol Tetranitrate (PETN), 2,4,6-Trinitrophenylmethylnitramine (TETRYL), 2,6-Dinitrotoluene (2,6-DNT), Polyamide (PA), and Trimethylolethane Trinitrate (TMETN). The method was developed for qualitative determination purposes. No previous methods were encountered in the literature regarding the simultaneous determination of these substances in a soil matrix.

The cleavage products for 2,6-DNT, TNT, picric acid, TETRYL, TMETN, RDX, HMX, PETN, and phenytoin (which is used as an Internal Standard (I.S.)) were investigated in MS/MS and the signals of mass-to-charge (m/z) ratios were optimized. MS/MS parameters and chromatographic methods were optimized by using a gradient ammonium nitrate: methanol mobile system and a C^{18} column. The samples were analyzed in LC/MS/MS with APCI negative ionization mode after a 30min single-step extraction procedure. The multiple reaction monitoring ions used were: 226.10 \rightarrow 88.20 for TNT, 377.90 \rightarrow 62.00 for PETN, 357.90 \rightarrow 61.80 for HMX, 181.20 \rightarrow 151.30 for 2,6-DNT, 240.70 \rightarrow 212.50 for TETRYL, 317.00 \rightarrow 61.60 for TMETN, 227.70 \rightarrow 197.50 for picric acid, and 283.40 \rightarrow 61.70 for RDX.

Selectivity-specificity, accuracy (recovery), linearity, and LOD and LOQ values were investigated. The chromatographic peaks were not affected by matrix and the other peaks. The intra-day precision limit was chosen as 15%. Samples including TNT, PA, HMX, TMETN, PETN, TETRYL, 2,6-DNT, RDX, and Phenytoin (I.S.) were eluted from the system within ten minutes without interfering with each other's channels. Average recovery obtained from the analyses of the soil samples, including the explosive 250.00, 500.00, 1,000.00ngg-1 explosive mix, both before and after extraction, were between 93.01% and 104.20% ($n \geq 6$). The method was linear in the concentration ranges of 58.00-1,000.00ngg-1 for PA, 241.50-1,000.00 ngg-1 for TNT, 13.20-1,000.00 ngg-1 for RDX, 22.00-1,000.00 ngg-1 for HMX, 100.00-1,000.00 ngg-1 for 2,6-DNT, 114.00-1,000.00ngg-1 for TETRYL, 97.00-1,000.00ngg-1 for PETN, and 190.00-1,000.00ngg-1 for TMETN. Regression coefficients for all calibration graphs were ≥ 0.99 . LOD and LOQ values obtained from the analyses of the soil samples including the explosive mix were between 8.92-161.22ngg-1 and 13.20-241.50 ngg-1, respectively.

As a result, an economical, fast, easy, repeatable, and selective method with low detection and quantification limit and high recovery was developed for the analysis of TNT, PA, HMX, TMETN, PETN, TETRYL, 2,6-DNT, and RDX in soil by using LC/MS/MS with APCI ionization.

LC/APCI-MS/MS, Explosive, Determination in Soil

B2 Raman Microspectroscopy of Body Fluid Traces: Intrinsic Method Selectivity

Igor K. Lednev, PhD, 1400 Washington Avenue, Albany, NY 12222*

After attending this presentation, attendees will have a better understanding of the recent advancements of a particular application of Raman spectroscopy. The implementation of advanced statistics for automatic analysis of spectroscopic data and the evaluation of the accuracy and reliability of the conclusions made will be discussed.

This presentation will impact the forensic science community by potentially having a great effect on the accuracy and effectiveness of biological stain analysis for forensic purposes.

The identification of traces of body fluids discovered at a crime scene is a major part of forensic investigation today. The three most common fluids found are blood, semen, and saliva, and there are several methods used currently to distinguish one from another. Blood can be presumptively tested by using different color spot tests, but these tests are destructive to the sample and can also result in false positives. Semen is similar in that there are destructive presumptive tests as well as confirmatory tests; however, saliva has no confirmatory tests. Most presumptive tests can be performed in the field, but some sample preparation such as extraction is often necessary. Most confirmatory tests must be done in the laboratory. The main problem with these tests is the destruction of the sample. The forensic community is in great need of a reliable, non-destructive, on-field method for identification of all common body fluids.

Raman spectroscopy is a technique that is increasing in popularity among the different disciplines of forensic science. Some examples of its use today involve the identification of drugs, lipsticks, and fibers, as well as paint and ink analysis. The theory behind Raman spectroscopy is based on the inelastic scattering of low-intensity, non-destructive laser light by a solid, liquid, or gas sample. Very little or no sample preparation is needed and the required amount of material tested with a Raman microscope can be as low as several picograms or femtoliters. A typical Raman spectrum consists of several narrow bands and provides a unique vibrational signature of the material. Typically, non-resonance Raman spectroscopic measurements do not damage the sample. The stain could be tested in the field and still be available for further use in the laboratory for DNA analysis. A portable Raman spectrometer is a reality that should now allow for identification at the crime scene.

The latest development of a new method for identification of body fluid traces using Raman spectroscopy combined with advanced statistics is reported in this study. Multidimensional Raman spectroscopic signatures of dry traces of sweat, vaginal fluid, semen, saliva, and blood have been reported earlier. The dry blood signature has been upgraded to eliminate possible photodamage.¹ The method was expanded for the application to semen stains on common substrates.² The differentiation of menstrual and peripheral blood with high confidence was demonstrated.³ Raman spectroscopy has also been shown to be effectively applied as a non-destructive technique for differentiating human blood from a wide survey of animal blood.⁴ A Partial Least Squares Discriminant Analysis (PLSDA) model was built from a training set of the near infrared Raman spectra from 11 species. Various performance measures, including a blind test and external validation, confirmed the discriminatory performance of the chemometric model, which demonstrated 100% differentiation. Most importantly, a satisfactory differentiation between 11 individual animal classes was demonstrated.⁵

This project was supported by Award No. 2011-DN-BX-K551 awarded by the National Institute of Justice, Office of Justice Programs, United States Department of Justice. The opinions, findings, and conclusions or recommendations expressed in this publication are those of the authors and do not necessarily reflect those of the Department of Justice.

B3 Individual Identification for Bones More Than 60 Years Old Using Autosomal SNPs on an Affymetrix® Chip

Sohee Cho, 28 Yongon-Dong, Chongno-Gu, Seoul 110-799, SOUTH KOREA; Soong Deok Lee, PhD, 28 Yongon-dong, Chongno-gu, Seoul, 110-799, SOUTH KOREA; and Jihyun Lee, 28 Yongon-Dong, Chongno-Gu, Seoul, SOUTH KOREA*

After attending this presentation, attendees will understand the usability of Single Nucleotide Polymorphisms (SNPs) for individual identification in cases with aged bone samples as well as the basic principles involved in the use of resequencing arrays through practical analysis of case work using an Affymetrix® chip.

This presentation will impact the forensic science community in cases such as mass disasters by introducing a promising DNA typing tool. Short Tandem Repeat (STR) typing is typically performed to estimate genetic relationships, such as paternity tests; however, the limited number of STR markers, even though expanded more than previously before, is not sufficient enough in some cases. For example, it is hard to get full STR alleles in degraded samples such as bone or enough differentiation in very closed genetic relationships like those in an isolated population where the STR markers are only now being analyzed. In these cases, a supplementary tool is necessary to increase the power of matching probability with additional markers. SNP analysis is promising in this respect as it can be designed to be short for easy amplification, even in degraded samples, and can easily be multiplexed.

A resequencing array containing 169 autosomal SNP markers, which are distributed throughout the autosome except for chromosome 21, was used in this study on an Affymetrix® platform. The DNA chip analysis was applied to 14 identification cases involving bones that had been buried when the Jeju 4.3 incident occurred in South Korea from 1948 to 1954. Each case was comprised of recovered bone from a putative father and blood from an individual believed to be their child or sibling. For each analysis, the 169 SNP markers were applied to multiplex Polymerase Chain Reaction in a tube, then hybridized to probes on a chip. The statistical parameters, such as cumulative matching probability or cumulative identity index, were represented on an Identity by Descent (IBD) basis.

When comparing markers among the typed SNPs, the resulting data showed approximately 50 to 125 SNPs were shared in pairs. The genetic relationship was confirmed in all of the identification case pairs with over 99.99% of cumulative matching probability. In addition, no instances of discordance of STR alleles in a pair were found.

This study demonstrated a successful evaluation of genetic relationships was possible on challenging bone samples using autosomal SNP marker DNA chip resequencing results. Given the outcome of this study, it is expected that this test could be applicable to forensic samples as a complementary tool.

Resequencing, Affymetrix® Chip, Single Nucleotide Polymorphism

B4 Development of Multiplexed Autosomal STR, Y-STR, and mtDNA Systems for Forensic Identification Using Next Generation Sequencing

Lotte Downey, MSc, MBA, 2800 Woods Hollow Road, Madison, WI 53711; Jaynish Patel, PhD, Promega, 2800 Woods Hollow Road, Madison, WI 53711; Spencer Hermanson, BS, Promega, 2800 Woods Hollow Road, Madison, WI 53711; Leta Steffen, PhD, Promega, 2800 Woods Hollow Road, Madison, WI 53711; Cynthia J. Sprecher, BS, 2800 Woods Hollow Road, Madison, WI 53711; Robert McLaren, PhD, Promega, 2800 Woods Hollow Road, Madison, WI 53711; and Douglas R. Storts, PhD, Promega Corporation, 2800 Woods Hollow Road, Madison, WI 53711*

After attending this presentation, attendees will understand how next generation sequencing can impact their workflow and provide an increased ability to deconvolute mixed samples.

This presentation will impact the forensic science community by providing more information from crime scene samples to enhance criminal investigations.

Next Generation Sequencing (NGS) is capturing significant interest in the forensic community because of its promise of greater mixture resolution and increased capacity for multiplexing. Three systems have been developed to enable forensic identification of samples using NGS. The PowerSeq® Auto System includes all loci in “Section A” of the proposed expanded Combined DNA Index System (CODIS) core, as well as two loci from “Section B” (TPOX and D22S1045) and two highly polymorphic pentanucleotide loci (Penta E and Penta D).¹ The combination of these 23 Short Tandem Repeat (STR) loci and amelogenin makes this multiplex an effective tool for human identification using NGS while maintaining compatibility with existing databases worldwide. The PowerSeq® Mito System includes reagents to produce a set of small amplicons for sequencing the mitochondrial control region. NGS allows laboratories access to mitochondrial DNA (mtDNA) analysis using a simpler, yet potentially high-throughput workflow. Increased mixture deconvolution and heteroplasmy resolution are achieved by deep sequencing coverage and digital read counts, compared to traditional sequencing methods. Additionally, the use of small amplicons to sequence the mitochondrial control region improves sequencing results from degraded samples.

A multiplexed system of autosomal STRs, Y-chromosomal Short Tandem Repeats (Y-STRs), and mtDNA will render more information from crime samples in a single assay. The developed multiplex system described here includes all loci from the PowerSeq® Auto System and the amplicons from the PowerSeq® Mito System combined into one multiplex, as well as 23 Y-STR loci for enhanced interpretation of mixed samples. This system is used in conjunction with the Illumina® MiSeq® System to generate a complete sequence analysis (STR genotype, STR repeat structure, mitochondrial haplotype, and SNP information) from a single amplification and sequencing reaction. Four different DNA samples for a total of 18 samples were typed using PowerSeq® Auto, resulting in 100% full profiles that are fully concordant with the profiles obtained through capillary electrophoresis. Two different DNA samples were typed using the PowerSeq® Mito System for a total of 14 samples, resulting in full concordance with profiles obtained through Sanger sequencing. Five libraries were analyzed with the multiplex of autosomal STRs, Y-STRs, and mtDNA and were found to be fully concordant.

Next-Gen Sequencing, DNA Mixtures, STRs and mtDNA

B5 Efficiency of Human DNA Isolation and Short Tandem Repeat (STR) Profiling From Burnt Teeth

Sara C. Zapico, PhD, Smithsonian Institution, Dept of Anthropology, NMNH, MRC 112, 10th & Constitution Avenue, NW, Washington, DC 20560; Joe Adserias, DDS, PhD*, C/ Balmes 62, Barcelona, SPAIN; and Douglas H. Ubelaker, PhD, Smithsonian Institution, Dept of Anthropology, NMNH, MRC 112, Washington, DC 20560*

After attending this presentation, attendees will have deeper insight concerning the efficiency of DNA profiling in burnt teeth.

This presentation will impact the forensic science community by providing a quantitative analysis for obtaining complete or partial DNA profiles from burnt teeth under controlled conditions of time and temperature.

Identification of a deceased individual is important from the relatives' viewpoint and is a vital factor in facilitating criminal investigations, inquests, and other tribunals. Mass disasters, aircraft or car accidents, and accidental deaths frequently involve the presence of fire.

The identification of human remains subjected to incineration depends on the degree of destruction of the remains, which is affected by the intensity and duration of the fire. One of the approaches for identification of burnt remains is genetic analysis. The genetic approach is usually unproblematic in cases of fire victims with conserved internal organs; however, extremely charred bodies frequently render highly degraded DNA, hampering Short Tandem Repeat (STR) analysis. Also, few studies focus on the possibility of amplifying authentic DNA from burnt remains. No consensus has been reached regarding the degree of cremation at which bone will still yield authentic DNA signals. Although previous studies have used similar temperature ranges (between 100°C and 1,000°C), the duration of fire exposure differs among these studies. In the studies developed on whole teeth and pulp DNA, the same problem is encountered: the temperatures were similar to those used in the bone studies and the durations of exposure varied. Therefore, more research is needed to evaluate the possibility of extracting DNA from burnt remains.

Since teeth are the hardest tissue of the human body and one of the most abundant types of biological remains available in forensic cases, the present study focused on the evaluation of the efficiency of DNA isolation from burnt teeth and the achievement of obtaining a DNA profile at different conditions of temperature and time exposure.

Twenty-eight healthy erupted third molars, aged 20 to 70 years, were collected from dental clinics. The Smithsonian Institution's ethical committee approved all procedures related to experimentation with human subjects. The teeth were divided into seven groups treated at different temperatures: 100°C, 200°C, 300°C, 400°C, 500°C, 600°C, and 700°C. The teeth in each group were treated at their assigned temperature for 1 minute, 5 minutes, 10 minutes, and 15 minutes, removing one tooth after each time period. Two non-burnt teeth were used as controls.

Control and burnt teeth were then mechanically ground and submitted to DNA extraction and quantification. Based on the quantification data, it was not possible to obtain DNA from the teeth subjected to 400°C for both 10 and 15 minutes, 500°C for 15 minutes, 600°C for 5 minutes and 700°C for 5, 10, and 15 minutes. To study the efficiency of obtaining DNA profiles, the following STRs were chosen: D7S820, D13S317, D5S818, CSF1PO, TPOX, TH01, vWA, D16S539, and FES/FPS, along with amelogenin. These regions were analyzed by SYBR® Green Real Time PCR. Each sample was tested in duplicate. The analysis of relative gene expression data was calculated using $2^{\Delta CT}$ method.

Quantitative PCR results were similar for all STRs tested. In the first temperatures and times, 100°C and 200°C, one and five minutes, it was possible to get amplification similar to the controls; however, in the majority of STRs, the amplification was very low from 300°C for one or five minutes onward. This DNA amplification was nearly undetectable, specifically in STRs located in an intron region, like TPOX, CSF1PO, TH01, and vWA. In contrast, the analysis of the amplification of the housekeeping gene used for the Quantitative Polymerase Chain Reaction (QPCR) quantification, Glyceraldehyde 3-Phosphate Dehydrogenase (GAPDH), showed that DNA for this region was amplified in all combinations of temperatures and times, finding highest Ct (meaning the least amplification) with the increase in temperatures and times. This indicates that even in burnt teeth subjected to high temperatures, it is possible to amplify DNA, at least housekeeping DNA; however, the data also shows that an STR profile would be difficult to obtain, probably due to the size of these regions which makes them more prone to degradation.

Criminalistics Section - 2015

The findings from this research provide a quantitative study for the achievement of obtaining a DNA profile from burnt teeth. Future research may be able to expand on these results, analyzing other potential DNA regions for identification under the same conditions.

Burnt Teeth, DNA Isolation, STR Profiling

B6 Age Estimation in Living Individuals Based on Photographs: Relevance in Cases of Pedopornography

Sindia Alves, Faculty of Medicine, Rua Larga 3004-504 Coimbra, Coimbra, PORTUGAL; Duarte N. Vieira, PhD, MD, Rua Antonio Jose de Almeida, No 117, Coimbra 3000-044, PORTUGAL; Francisco Corte-Real, PhD, Center Branch, National Institute of Legal Medicine, Largo da Sé Nova, 3000-213 Coimbra, Coimbra, PORTUGAL; Ricardo Vicente, MD, Faculty of Sciences and Technology, Rua Arco da Traição, Coimbra, PORTUGAL; and Eugenia Cunha, PhD, Universidade de Coimbra, Dept of Life Sciences, Forensic Sciences Centre, Coimbra 3000-456, PORTUGAL*

After attending this presentation, attendees will better understand how to test the accuracy of age estimation on the basis of facial morphology.

This presentation will impact the forensic science community by providing results from an experiment in an area with very little previous research. This presentation, accomplished through forensic anthropology, will alert professionals responsible for age estimation in cases of child pornography to be careful in the methodologies used, since such conduct may cause judicial errors.

Age estimation of child pornography victims has played an essential role in forensic practice, due to the high number of pedopornography cases, for decades. In order to address this problem, experts are often called upon to testify in court. The goal of this study is to test the accuracy of age estimation on the basis of facial morphology.

In this study, 12 evaluators (three forensic anthropologists, three forensic pathologists, three pediatricians, and three “non-experts”) analyzed 128 photographs of the faces of minors between the ages of one and 17 years (83 females and 45 males) to identify the age of each child. Each evaluator completed four observations, days apart, which were organized into two groups. In the first two observations, evaluators were asked to identify the age of each child and, in the last two, were asked to additionally indicate the most relevant facial characteristic for determining the age estimation for the child in each photograph.

The results confirmed that the best values obtained (87.92%) were associated with age estimation of younger individuals (<12 years old). When assessing the reliability of evaluators’ answers, reliable results (79.51%) were only observed after the age range of ± 2 years. After examining the influence of some parameters in the estimation obtained (sex, number of children, professional status of the evaluators, and sex of the study subjects), it was observed that, for real age, only the evaluator’s professional status and the sex of the study subjects did not influence age estimation. On the other hand, for age groups, the results showed that professional status was the only parameter influencing the correct estimates (highlighting the better results of the pediatricians). With respect to what the evaluators felt was the most relevant facial characteristic for age estimation of the children observed in each of the photographs, the “general appearance of the face” stood out, although it was more often associated with incorrect estimates (75.39%).

Overall, even though Portugal has no software that allows the analysis of age estimation based on photographs, new criteria should be implemented to improve this type of methodology in order to avoid judicial error.

Age Estimation, Child Pornography, Facial Images

B7 Maximize Information From Your Mixture Samples Using a Combined Autosomal STR and Y-STR Multiplex System

*Rohaizah James, PhD**, 2800 Woods Hollow Road, Madison, WI 53711; *Martin Ensenberger, PhD, Promega*, 2800 Woods Hollow Road, Madison, WI 53711; *Patricia Fulmer, PhD, Promega*, 2800 Woods Hollow Road, Madison, WI 53711; *Kristy Lenz, MS, Promega*, 2800 Woods Hollow Road, Madison, WI 53711; *Dawn Rabbach, PhD, Promega*, 2800 Woods Hollow Road, Madison, WI 53711; *Cynthia J. Sprecher, BS*, 2800 Woods Hollow Road, Madison, WI 53711; and *Douglas R. Storts, PhD, Promega Corporation*, 2800 Woods Hollow Road, Madison, WI 53711

After attending this presentation, attendees will be able to evaluate the potential benefit of using a combined autosomal Short Tandem Repeat (STR) and Y-chromosomal Short Tandem Repeat (Y-STR) marker set for analyzing mixture samples.

This presentation will impact the forensic science community by describing a less expensive and quicker STR method for analyzing casework samples.

The PowerPlex® Fusion™ 6C System is a six-color STR system for simultaneously amplifying 23 autosomal loci, three Y-STR loci, and amelogenin. The 20 required (amelogenin, D18S51, FGA, D21S11, D8S1179, vWA, D13S317, D16S539, D7S820, TH01, D3S1358, D5S818, CSF1PO, D2S1338, D19S433, D1S1656, D12S391, D2S441, D10S1248, and DYS391) and three recommended (TPOX, D22S1045, and SE33) proposed expanded Combined DNA Index System (CODIS) core loci are combined with Penta D, Penta E, DYS570, and DYS576 to give this system a discriminatory power ($PI=1.80 \times 10^{-32}$) that is more than 10^8 -fold higher than that for the 20 required expanded CODIS core loci ($PI=9.35 \times 10^{-24}$). With DYS391 and nine autosomal loci being less than 250bp, the additional genetic information obtained with this 27-loci STR system will be extremely useful for analyzing degraded samples, where even a partial profile would be informative.

The DYS391 locus is included in the proposed expanded CODIS core loci for verification of gender in amelogenin null samples; however, it has one of the lowest locus variability values and does not significantly increase discriminatory power. In contrast, DYS570 and DYS576 have two of the highest locus variability values within American subpopulations and contribute more to the system's discriminatory power than DYS391. Additionally, because they are rapidly mutating Y-STRs, DYS570 and DYS576 provide the potential for separating close male relatives and further improving useful information from a single STR analysis. These three Y-STR loci will allow more confident determination of the number of male contributors in complex mixtures without the need for a separate Y-STR analysis, thus saving time and money.

This system is designed for 1ng of optimal input DNA template. The average peak height ratio is over 90% with one ng DNA template and remains high (80%) with as low as 100pg DNA template. It is very sensitive and is capable of calling $98 \pm 21\%$ (average \pm SD) of alleles with 100pg DNA template. Even with as low as 50pg DNA template, $77 \pm 17\%$ (average \pm SD) of alleles are called. The system is also resistant to very high concentrations of PCR inhibitors. In reactions containing up to 0.5mM hematin, 100% of alleles are called with this system. Improved resistance to humic acid and tannic acid is also observed.

To improve laboratory workflow efficiency, this system is designed for use with both casework samples as well as with reference and database samples. Direct amplification of blood or buccal samples on multiple substrate types such as FTA® card, non-FTA® cards, and swabs eliminates the extraction process, which saves time and money. To further save time and improve efficiency, automation methods are available for multiple liquid-handling platforms which minimize potential cross-contamination and result in more than a 95% first-pass success rate.

STR, Y-STR, Casework

Criminalistics Section - 2015

B8 Self-Generating Robot Worklists and Complete Sample Traceability Through Laboratory Information Management Systems (LIMS) Integration and Barcodes

Jennifer Duncan, BS, Texas Department of Public Safety, 12230 West Road, Bldg C, Houston, TX 77065; Jenna Dunton, MS, Texas Department of Public Safety, 12230 West Road, Bldg C, Houston, TX 77065; Kathleen M. McKinney, MS, 402 West IH 30, Garland, TX 75043; Alexis Meeker, MFS, Texas Dept of Public Safety, Crime Lab Houston, 12230 West Road, Bldg C, Houston, TX 77065; Andrea R. Smith, BS, 12230 West Road, Houston, TX 77065; Andrew P. McWhorter, MFS, 12230 West Road, Houston, TX 77065; Tanya Dean, BS, Texas Department of Public Safety, 12230 West Road, Bldg C, Houston, TX 77065; Kristi Wimsatt, 12230 West Road, Houston, TX 77065; and Keith Gibson, BS, Texas Department of Public Safety, 12230 West Road, Bldg C, Houston, TX 77065*

After attending this presentation, attendees will be familiar with a customized robotic liquid handling system which is capable of self-generating worklists through the use of barcodes and LIMS integration.

This presentation will impact the forensic science community by informing forensic DNA laboratories about an automated system which has integrated the LIMS database and utilizes barcodes to improve sample traceability and reduce analyst input errors.

The Texas Department of Public Safety (TX DPS) Crime Laboratory in Houston, TX, recently procured a Hamilton AutoLys STARplus for the purpose of automating the entire DNA workflow, including lysis and substrate removal, on a single platform. Sample traceability is of utmost importance to the TX DPS Crime Laboratory system; therefore, the use of barcodes and LIMS integration was essential to this project. The instrument was integrated with the DPS LIMS database which enabled self-generating worklists with built-in data verifications and complete sample traceability through the use of 2D barcodes.

The STARplus system was modified by Hamilton to accommodate both 2D and 1D barcode reading systems. The 2D barcode on the bottom of the AutoLys tube is registered in the LIMS system to a specific item of evidence while another 2D barcode is generated for the label on the 1.5mL tube that will be used for the final storage of the purified DNA extract. Both barcodes are associated with the same sample, so the sample's movements are recorded in its chain of custody as it makes its way through the DNA process. To work around limitations of the current LIMS system, samples are batched together using a barcoded mobile container.

Through the use of barcodes, data verification measures, and custom programming by the Hamilton Automation Applications engineer, the instrument has the ability to ensure the proper number of reagent blanks, distinguish "known" and "questioned" samples to prevent co-extraction, determine the length of the lysis buffer incubation and elution volume during extraction based on sample type, verify user input for extraction kit information, and create self-generating worklists. These measures reduce both the amount of input needed from the analyst and the potential for transcription errors.

In order to store and access quantification results, a custom-built quant value database was developed by Hamilton for TX DPS Houston. When the robot creates a worklist for the normalization/amplification method, it queries the LIMS database for sample information, and queries the quant value database for quant values. The method then combines the data to generate a worklist.

Finally, TX DPS Houston has developed a separate spreadsheet workbook for each method that uses output files generated by the robot to create casefile worksheets. All sample information is imported into the spreadsheet workbook, requiring the analyst to input only the occasional date and run identifier. The worksheets also offer extra functionality including highlighting samples from a specific case, printing, and selecting capillary electrophoresis instruments and injection times.

Overall, the Hamilton AutoLys STARplus has met expectations and has proven to be reliable in terms of ease of use for workflow and sample traceability.

Automated DNA Workflow, Barcode Traceability, LIMS

B9 Obtaining DNA-Short Tandem Repeat (STR) Profiles From Evidentiary Samples With Extremely Limited Amounts of DNA

Alexander Sinelnikov, PhD, Independent Forensics, 500 Waters Edge, Lombard, IL 60148; Pravatchai W. Boonlayangoor, PhD, Independent Forensics, 500 Waters Edge, Lombard, IL 60148; and Karl Reich, PhD, Independent Forensics, 500 Waters Edge, Lombard, IL 60148*

After attending this presentation, attendees will have learned about a systematic approach to obtaining DNA-Short Tandem Repeat (STR) profiles from samples with very limited amounts of DNA. Forensic science practitioners will have learned about an optimized method for: (1) the collection of small biological samples; (2) the extraction of DNA from these samples; (3) the purification of DNA from such samples; and, (4) the post-Polymerase Chain Reaction (PCR) purification and concentration of amplicons. The final goal of this sequence of techniques is to obtain DNA profiles from the smallest possible forensic samples; this study has fully optimized the individual steps and introduced a method that utilizes the entire PCR reaction for electrokinetic injection on Capillary Electrophoresis (CE) instrumentation.

This presentation will impact the forensic science community by describing the procedure that can be used to successfully obtain DNA-STR profiles from very challenging forensic samples (sometimes referred to as “touch DNA” samples) like single fingerprints, single bullets, and small areas of worn clothing.

For a variety of reasons, both legal and criminalistic, forensic practice increasingly demands DNA profiles from ever-smaller (in terms of DNA content) samples. This trend includes testing “gun swabs,” swabs from bullets (fired and unfired), exploded bomb parts (including Improvised Explosive Devices (IEDs)), zipper pulls, door knobs, hammer handles, and even latent ridge impressions (fingerprints). Many of these kinds of samples fail to provide useful DNA profiles using current methods. This is primarily due to losses of biological material during the collection, DNA extraction, and purification steps. Another contributing factor in failing to obtain a useful DNA profile is that only a fraction (typically <6%) of the multiplex STR PCR reaction is used for CE analysis. The procedure discussed here corrects all of these deficiencies.

Specifically, the protocol includes the following materials and methods. Larger objects (e.g., aluminum cans) and absorbing surfaces (e.g., clothing) are swabbed with regular-sized swabs. Small objects (e.g., individual fingerprints, bullets, etc.) are swabbed with user-produced mini-swabs. Mini-swabs are made by deliberately truncating the swab head to approximately ¼-½ of the regular cotton swab. Regular cotton swabs were wet with 50µL and mini-swabs with 10-20µL of collection buffer containing a low concentration of detergent. Following collection, regular swabs were saturated with 70µL and mini-swabs with 40µL of lysis buffer that includes detergent and Proteinase K. Swabs were incubated at 56°C for one hour. The lysate was collected by centrifugation in a spin-basket and loaded onto a column filled with polyamide resin. DNA was purified on the column at 4,000 Relative Centrifugal Force (RCF) for two minutes. Purified DNA was either amplified directly or concentrated three- to four-fold under vacuum centrifugation. Following PCR amplification using a commercial forensic multiplex kit (the use of additional PCR cycles is not recommended), an AmpliconRx™ kit was used for post-PCR purification and concentration of the entire PCR reaction, as this further increases (by up to approximately 20 times) the final CE signal.

The current study shows that when combined into a complete protocol, this integrated procedure for collection, extraction, purification, and post-PCR clean-up, concentration significantly increases the sensitivity of obtaining DNA profiles from low-template (touch DNA) samples. Specifically, the limit of detection of this method was tested by applying progressively smaller amounts of a control DNA solution to a non-absorbent surface, allowing the deposition to dry, and then collecting and processing as described. These experiments demonstrated that full profiles (26 alleles) could be reproducibly obtained from as little as 62.5pg of starting DNA material on a non-absorbent surface.

Testing of this method has continued using developed and undeveloped fingerprints on a variety of surfaces. Examples of some successfully profiled items that will be presented are: (1) three poorly developed fingerprints deposited on an aluminum can — full profile (28 alleles); (2) a single well-developed fingerprint on a plastic surface — 26 out of 27 expected alleles; and, (3) an unfired bullet, loaded into a magazine, retrieved, and tested — 25 out of 28 expected alleles.

Touch DNA, Sample Collection, DNA Purification

B10 Validation and Incorporation of RapidHIT™ Technology Into Routine Forensic DNA Casework

Gray Amick, PhD, RCSD, 5623 Two Notch Road, Columbia, SC 29223*

After attending this presentation, attendees will understand that the RapidHIT™ instrument can be used for forensic DNA evidence in addition to buccal swabs for routine forensic analysis.

This presentation will impact the forensic science community by educating analysts about the ability of this system to be used for routine forensic DNA casework.

In December of 2013, the Richland County Sheriff's Department (RCSD) acquired a RapidHIT® (IntegenX®) instrument for fully automated sample-to-answer Short Tandem Repeat (STR) -based human identification. This system produces a DNA profile from swabs or cuttings in approximately two hours. The focus of this system in the scientific field has been on its use for DNA profiling of buccal swabs for a myriad of applications. The laboratory validated and implemented this instrument for full integration into routine forensic DNA casework to include buccal swabs from suspects as well as evidence swabs and cuttings. During validation, a study was performed to assess usable sensitivity (ability to produce a profile for exclusion or inclusion) of the system for evidence samples. Of the 28 different samples evaluated (drinking straw, gum, pulled hair, cigarette butt paper, drink can, steering wheel, door handle, foam cup, bitemark, jacket collar, cell phone, etc.), 22 produced full (16 of 16 loci) profiles, four produced partial profiles (11 to 15/16 loci), and two produced no profiles (whole cigarette butts were placed into the sample cartridge which resulted in interference of the extraction). Upon completion of validation, RapidHIT® was approved for casework and has been successfully utilized for several different case types.

A serial burglary (three related burglary cases), a criminal sexual-conduct case, an aggravated armed robbery/attempted murder case, and multiple suspect standards for the local database have been analyzed with RapidHIT®. The burglary cases consisted of two blood swabs and a bloodstained cutting from a leather pouch from the crime scenes as well as a buccal swab from a suspect. These were analyzed on a RapidHIT® utilizing PowerPlex® 16 HS chemistry using the "Other" protocol. Complete (16 of 16 loci) profiles were generated from the evidence and the suspect's buccal swab. Resulting DNA profiles were interpreted after the two-hour run and the results were communicated to the investigator after technical review. The profiles generated from the three different crime scenes matched the suspect. As a result, the suspect was arrested and charged with 2nd-degree burglary and larceny. Evidence from the attempted murder case consisted of swabs from the suspect's pants, shoes, and a victim's buccal swab. These were run on the RapidHIT® utilizing GlobalFiler® Express chemistry with the "Other" protocol. Complete (22 of 22 STR loci) profiles were generated from the evidence and victim's standard. Profiles generated from the suspect's clothing matched the victim. After technical review, findings were communicated to the investigator and the suspect was arrested for attempted murder and armed robbery.

The RCSD successfully renewed its American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB) -International accreditation in June of 2014. RapidHIT® technology was in place, reviewed, and memorialized during this assessment. Currently, the results generated from this system are used for investigative information. If the customer requires a laboratory report, samples are re-analyzed utilizing the conventional DNA profiling method. Once the quality standard requiring human quantitation is modified to accommodate this technology, any profile generated from this instrument could be considered eligible for the Combined DNA Indexing System. The RCSD DNA laboratory views this instrument as an evolution in DNA typing technology.

Rapid DNA, Forensic DNA, Casework

B11 A “Whodunit” Solved Utilizing Mixture Interpretation Software With Quantitative Genotyping

Melissa M. Chila, MS, United States Army Criminal Investigation Lab, Bldg 925, Forest Park, GA 30297; and Tim Kalafut, 4930 N 31st Street, Forest Park, GA 30215*

After attending this presentation, attendees will appreciate how useful touch DNA samples can be and gain an understanding of how mixture interpretation tools can be pivotal in deconvoluting difficult mixtures. The algorithms used in the ArmedXpert™ software will also be introduced.

This presentation will impact the forensic science community by demonstrating how a complex DNA mixture from a perplexing case was able to be interpreted, using quantitative genotyping, and led to a useful investigative lead.

Touch DNA is DNA which is deposited when someone touches or comes in contact with an item and leaves sloughed off skin cells behind. It is usually present in very low quantities and full DNA profiles are often difficult to obtain due to the low number of cells which are usually deposited. Because of the nature of touch DNA samples, it's very rare that a Combined DNA Index System (CODIS) -worthy profile is developed; however, with the help of mixture interpretation software, difficult mixtures, such as those obtained when swabbing for touch DNA, can more readily be interpreted and can result in useful investigative information.

In 2012, the United States Army Criminal Investigation Laboratory (USACIL) received a case involving the abduction of a young child. A little girl was playing on a playground when she was approached by an unknown male who proceeded to kidnap her. Shortly after being captured, the child was able to flee to safety; however, even after she gave a description of the man, investigators had no idea who the abductor was. The child's pants were subsequently submitted to the laboratory and, during analysis, the pockets were swabbed for touch DNA since it was alleged that the assailant touched that area.

The resulting DNA profile was analyzed using ArmedXpert™, a mixture interpretation software tool that was developed in-house and for which USACIL currently holds a patent. It uses a simple deconvolution strategy based on three rules: (1) shared alleles are shared in proportion to the unshared alleles; (2) where possible, peak height ratios are defined as 100%; and, (3) minimum allele heights are maintained. This software has been invaluable in streamlining the analysis and interpretation process. It has also provided a relatively high level of consistency in final results as determined by the statistical analysis of mixed DNA profiles used during internal competency testing.

With the help of the mixture interpretation software, the DNA profile obtained from the pants' pockets was able to be interpreted as a mixture of three individuals where the owner could be assumed, a family member could be identified, and a full unknown male DNA profile could be teased out for CODIS submission. In the months following case completion, approximately 150 standards were submitted for comparison; however, no matches were made. Finally, months after the unknown profile was uploaded to CODIS, it hit on an arrestee who has since accepted a plea deal and is currently serving 25 years.

Touch DNA, Complex Mixture, Mixture Software

B12 Database Samples Warranting a Closer Look and Examination of the D8S1179 Locus

Amanda J. Hoffman, MS, Marshall University Forensic Science Center, 1401 Forensic Science Drive, Huntington, WV 25701; and Jason Chute, MSFS, 1401 Forensic Science Drive, Huntington, WV 25701*

After attending this presentation, attendees will have closely observed two samples that originally produced profiles requiring additional examination for questionable allele calls at the D8S1179 locus. Attendees will see that in addition to standard practices employed at the Marshall University Forensic Science Center (MUFSC), steps were needed to determine the true genotypes for each of these samples in question.

This presentation will impact the forensic science community by enlightening attendees that analysts should be very aware that profiles produced may require additional examination due to inconsistencies or questionable calls. It is imperative to ensure that the true DNA profiles for each sample will be uploaded into local, state, and federal databases.

The original samples were previously spotted on Whatman® FTA® blood cards at the West Virginia State Police Forensic Laboratory (WVSPFL) and processed using the direct amplification method with PowerPlex® 16 HS employed at the MUFSC. These two database samples required more lab work due to problems with an allele call, a peak height ratio, and dropout at the D8S1179 locus.

Sample A and Sample B (generic sample names used in place of identifying the barcodes used in processing) were extracted and amplified using PowerPlex® 16 HS, PowerPlex® 16, and AmpFISTR® Identifiler® Plus. Sample A was initially direct amplified using the Powerplex® 16 HS kit resulting in an Off Ladder (OL) peak at the D8S1179 locus with a height of 704 RFU, a size of 225.08, and a calculated call of a 12.3. When comparing the sample with the ladder, the math came out to: $225.79 - 225.08 = 0.71$ on one side of the ladder and $225.08 - 221.77 = 3.31$ on the other side of the ladder, resulting in the call of a 12.3. This microvariant has been seen at the MUFSC six times and on STR base three times, leading an analyst to believe this could be a true call. The calculations resulting in the 12.3 call did seem a little far off from the normal OL/microvariant calculation normally seen. Normally, when calculated, the OL/microvariants are closer to a “1” nucleotide difference; however, based on the analysis, the sample appeared to have an allele call of 8,12.3 at D8S1179. Similar results were obtained from a cutting that was extracted on the EZ1® robot resulting in the 8 and 12.3 at D8S1179.

Sample A was subsequently amplified with Identifiler® Plus with a 1.0µl load of the neat extract, with a target of 1.933ng. With this kit, the allele in question fell into the 13 bin, resulting in a 8,13 call for the D8S1179 locus. In this testing, the 13 allele had a height of 1688 RFU and a size of 143.84. These Identifiler® Plus kit results led to the previous Powerplex® 16 HS kit results being questioned. Additional processing of Sample A was completed by the assistance of the National Institute of Standards and Technology (NIST) to obtain a profile that could be submitted to the West Virginia State Police for upload into the Combined DNA Index System (CODIS). The final and true allele calls for Sample A at the D8S1179 locus were determined to be an 8 and 13.

Sample B originally appeared to be homozygous at the D8S1179 locus with a 12,12 allele call, but close examination of the data caused the analyst to question whether there was possible allelic dropout. This sample would normally pass because the homozygous allele passed the stochastic threshold at the MUFSC. More laboratory work concluded that this sample did in fact have a sister allele of a 14 at this locus. This sample had to be extracted and amplified using PowerPlex® 16 HS, PowerPlex® 16, and AmpFISTR® Identifiler® Plus to obtain the true genotype.

This study will present the steps and processes taken to obtain successful and true profiles and the initial reasons for further examination of each sample. Each profile produced will be highlighted and explained for each amplification of the two samples. It is recommended that persons in the field are familiar with DNA analysis of single-source reference samples, direct amplification, and traditional methods of extraction and amplification, as well as peak height ratios and dropout.

DNA, Database, Microvariant

B13 Separation of Epithelial Cell Mixtures Using Fluorescently Labeled Antibodies and Flow Cytometry

*Cristina E. Stanciu, BS**, Virginia Commonwealth University, 1015 Floyd Avenue, Rm 2015, Richmond, VA 23284; *Ye Jin Kwon, BS**, 640 Worcester Road, #502, Framingham, MA 01702; *Sarah R. Ingram, BS*, Virginia Commonwealth University, 1015 Floyd Avenue, Rm 2015, Richmond, VA 23284; *Eduardo E. Bustamante, BS*, Virginia Commonwealth University, 1015 Floyd Avenue, Richmond, VA 23284; *Jamie Lynn Sturgill, PhD*, 1100 E Leigh Street, Rm 4013, Richmond, VA 23298; *Sarah J. Seashols, PhD*, Virginia Commonwealth University, Dept of Forensic Science, PO Box 843079, Richmond, VA 23284-3079; *Tracey Dawson Cruz, PhD*, Virginia Commonwealth University, 1015 Floyd Avenue, PO Box 843079, Richmond, VA 23284; and *Christopher J. Ehrhardt, PhD*, Virginia Commonwealth University, Dept of Forensic Science, 1015 Floyd Avenue, Rm 2015, Richmond, VA 23284

The goal of this presentation is to introduce attendees to a novel molecular technique that utilizes fluorescent antibody probes that target antigens within the Major Histocompatibility Complex (MHC) on epithelial cell surfaces. Attendees will also learn how antibody hybridization can be coupled to flow cytometry to provide rapid separation of targeted cell populations from a forensic mixture.

This presentation will impact the forensic science community by introducing a high throughput, non-destructive method for generating single-source DNA profiles corresponding to each contributor of an epithelial cell mixture. The technique can assist forensic caseworking units by providing an alternative to complex profile interpretation procedures, thereby reducing analytical bottlenecks and loss of evidence.

Previous research has shown the application of flow cytometry coupled to antibody probes targeting the Human Leukocyte Antigen (HLA) system for selectively isolating individual cell populations from a blood mixture to generate single-source Short Tandem Repeat (STR) profiles. The goal of this research was to test this technique against various types of epithelial cell mixtures for resolving individual contributor profiles. Due to its efficacy in earlier studies, an antibody probe complementary to the A*02 allele was chosen for all experiments. Hybridization experiments were conducted on both buccal cell mixtures and contact epithelial cell mixtures. Results from buccal cell mixture hybridization demonstrated that this cell type has intrinsically high levels of fluorescence which can interfere with the signal originating from specific probe-antigen interactions on the cell surface; however, detailed statistical analysis of fluorescence histograms did indicate greater shifts in cell fluorescence when donor cell populations were either heterozygous or homozygous for the A02 allele. This suggests that separation of labeled cell populations is still possible even if antibody reactivity is not strictly a function of HLA genotype.

In the second experiment, hybridization of the A02 probe was tested against contact epithelial cells. Cells were sampled from the stratum corneum of the epidermal layer from four different individuals representing a range of HLA types. Hybridization results showed little to no interaction with the cell surface across all donors tested. Preliminary experiments using enzymatic digestion of cell surface prior to probe hybridization, as well as novel types of surface antibodies, indicate that these may be effective strategies for enhancing differential labeling and separation of individual cell populations from contact epithelial mixtures. Because epidermal cells and buccal cells showed drastically different reactivity to A02 probe, mixtures containing these two cell types were analyzed. Two-person mixtures containing buccal cells from one contributor and epidermal cells from a second contributor produced two distinct cell populations after antibody hybridization that were easily resolved by flow cytometry. When the labeled cell population (i.e., buccal cells) was separated by Fluorescence Activated Cell Sorting (FACS), the STR profile was identical to its single-source profile across all six STR loci tested. This suggests that HLA antibody probes have the potential to resolve complex mixtures containing different sources of epithelial cells (buccal cells from skin) which may aid in the analysis of certain types of forensic cases.

Mixture, Flow Cytometry, STR Profiling

B14 Additional Criteria for Identification of Gasoline in Fire Debris Samples

Jeanet Hendrikse, MSc, Netherlands Forensic Institute, Laan van Ypenburg 6, The Hague 2497GB, NETHERLANDS*

After attending this presentation, attendees will understand new characteristics of gasoline which may support the identification of residues of gasoline in fire debris casework.

This presentation will impact the forensic science community by adding criteria, to the minimum criteria described in literature, for the identification of gasoline in fire debris casework.

Gasoline is a complex refinery blend product of crude oil. Due to its low flash point, it is extremely flammable and therefore a favorite liquid for arsonists.

The identification of residues of gasoline in fire debris samples can be challenging. The composition of gasoline is defined and is controlled by physical properties, while its presence in fire debris is based on the identification of its chemical composition. External factors may add to the complexity. Part of the gasoline may be lost due to evaporation, the release of background components from the burnt/pyrolyzed debris materials may interfere and either alter the composition of the gasoline residues present or may show resemblances in composition with gasoline, and the presence of bacteria and fungi may partially decompose the composition of the gasoline residues present.

Fire debris experts must have a broad knowledge on both the (variation in) the chemical composition of gasoline and on the factors that may affect this composition or may show resemblances with this composition. The latter is extremely important as a way to avoid false positive identifications.

Different guidelines can be found in literature on the identification of gasoline in fire debris samples. These include minimum criteria that should be met for a positive identification and warnings in order to avoid a false positive conclusion. These minimum criteria focus on the main compounds in gasoline including the aromatics and the more volatile alkanes with the necessity of both being present with aromatics usually more abundant than alkanes. It is important to note that their Gas Chromatographic (GC) patterns may vary from batch to batch. Due to this variation, a comparison to reference gasoline(s) is recommended for a positive identification. These minimum criteria are still somewhat general. Additional criteria that may support a positive identification without having to compare to the compositions of reference gasoline(s) on a case-to-case basis would therefore be most welcome and can — by opinion — be found by looking carefully at the way gasoline is produced.

Some gasoline blends are primarily added or produced as blend-product for gasoline: these blends are the octane enhancers. These can be oxygenates and/or the alkylate product from the alkylation refinery process. Typical oxygenates that may be encountered in gasoline are ethanol, Methyl Tert-Butyl Ether (MTBE), Ethyl Tert-Butyl Ether (ETBE), Tertiary Amyl Methyl Ether (TAME), and/or Tertiary Amyl Ethyl Ether (TAEE). The combination of oxygenate(s) in gasoline may vary from blend to blend and their use may be restricted by country legislations. The alkylate product usually consists of branched C₈-alkanes from the 4/4-alkylation (including iso-octane, 2,2,4-trimethylpentane) and/or branched C₇-alkanes from the 3/4-alkylation, and is different in composition from the C₇- and C₈-alkanes in crude oil and found in “straight-run” light petroleum distillates. The alkylate alkanes (in particular the C₈-alkanes) can therefore be considered characteristic for gasoline, despite some variation in their pattern from gasoline blend to blend.

Based on the national reference collection of gasoline, the impression is that most, if not all, gasolines today contain either one or more oxygenates or an alkylate fraction as octane enhancer. To test whether this also applies to gasolines in other countries, a total of 48 gasolines from 11 different European countries (Netherlands not included) were collected with help from European forensic colleagues and analyzed. Overall, 47 out of the 48 were observed to contain an octane enhancer. One gasoline from Scotland did not; this gasoline contained a naphtha fraction instead.

In the identification of gasoline in fire debris samples, adding the presence of an octane enhancer as minimum criteria for a positive identification is recommended: either 4/4-alkylate (C₈-isomers, including iso-octane) and/or oxygenates (e.g., MTBE, ETBE, TAEE), whereas the C₈-pattern and oxygenate combination may vary from batch to batch. Depending on the laboratory method(s) employed, they can still be recovered from fire debris samples, even when the gasoline residues show significant weathering.

Gasoline, Identification Criteria, Fire Debris Analysis

B15 A New Headspace-Mass Spectrometry Method for the Identification of Ignitable Liquids in Fire Debris Analysis

*Marta Ferreiro-Gonzalez**, Avenida Juan Ramon Jimenez, 38, Puerto Real, Cadiz 11510, SPAIN; Fernandez-Barbero, Unlisted; Jose Angel Alvarez, PhD, University of Cadiz, Dept of Analytical Chemistry, Faculty of Sciences, Apartado 40, Puerto Real 11510, SPAIN; Jesus Ayuso, PhD, University of Cadiz, Dept of Physical Chemistry, Faculty of Sciences, Apartado 40, Puerto Real 11510, SPAIN; Miguel Palma, PhD, University of Cadiz, Dept of Analytical Chemistry, Faculty of Sciences, Apartado 40, Puerto Real 11510, SPAIN; and Carmelo G. Barroso, PhD, University of Cadiz, Dept of Analytical Chemistry, Faculty of Sciences, Apartado 40, Puerto Real 11510, SPAIN

After attending this presentation, attendees will understand the importance of developing new analytical techniques for the identification of accelerants in arsons. They will realize how Headspace/Mass Spectrometry (HS/MS) technique can help in fire debris investigation which does not require sample preparation.

This presentation will impact the forensic science community by providing a green analytical technique for the identification of Ignitable Liquid Residues (ILRs) in fire debris. Apart from the speed of the analysis and the fact that the sample does not require sample pre-concentration, this technique also has good accuracy, is low cost, is easy to handle for routine analysis, and does not produce any residues as solvents are not used.

In arsons, accelerants such as ignitable liquids are commonly used to initiate or accelerate a fire. Therefore, the detection of ILRs at fire scenes is a key step in the investigation.¹ The most commonly used ignitable liquids are petroleum-based products like gasoline, diesel fuel, or kerosene as they are easy to obtain and easy to ignite.² In some cases, traces of ignitable liquids may remain at the fire scene and these could be matched to samples that are associated with the suspect. The identification of the type of ignitable liquid is very useful information for investigators when there is a suspected arsonist.

Gas Chromatography/Mass Spectrometry (GC/MS) is the most used analytical technique for the analysis of ILRs in fire debris. Indeed, American Society for Testing and Materials (ASTM) International provides guidelines for the identification and classification of ILRs from fire debris by using GC/MS.³ Before chromatographic analysis, it is necessary that the ILR be in a vapor or volatile form, thus a prior suitable sample preparation step of the ILR from fire debris samples is required. Different sample preparation standard practices have been approved by ASTM International for isolating the ILR. Passive headspace concentration with adsorption on Activated Carbon Strips (ACS) is currently the most commonly used method for isolating ILRs from fire debris because of its sensitivity, ease of handling, and because it is not non-destructive.^{4,6} The drawback of this method is the need of a solvent such as Carbon Disulfide (CS₂) for the desorption of the compounds from the ACS, which is extremely hazardous.

In this study, a new analytical method based on a Headspace/Mass Spectrometry (HS/MS), also known as electronic nose, for the analysis of ILRs is presented. The working conditions for the HS/MS analytical procedure were optimized using different fire debris (wood burned with gasoline, diesel, and citronella oil). The variables optimized included incubation temperature and incubation time. The optimal conditions were as follows: 115°C and 15 minutes. The optimized method was applied to a set of fire debris. To simulate a post burn, samples of several ILs (gasoline, diesel, citronella oil, kerosene, and paraffin oil) were used to ignite different substrate (wood, cotton, cork, paper, and paperboard). Chemometric methods (Hierarchical Cluster Analysis (HCA) and Linear Discriminant Analysis (LDA)) were applied to the MS data (45-100m/z). At first instance, HCA was enough to perform a correct classification of different ILRs.

Compared to the current methods, HS/MS does have specific advantages. Apart from the speed of the analysis and the fact that the sample does not require sample pre-concentration, this technique also has good accuracy, low cost, is easy to handle for routine analysis, and does not produce any residues because solvents are not used. This technique can be considered as a green technique for fire debris analyses.

Fire Debris, Ignitable Liquids, Headspace-Mass Spectrometry

B16 The Use of Isotope Dilution Inductively Coupled Plasma/Mass Spectrometry (ICP/MS) for Precise and Accurate Determination of Elemental Concentration of Trace Elements in Float Glass Standards (FGS1 and FGS2)

Stefan Becker, PhD, Bundeskriminalamt, Forensic Science Institute, KT 4, Wiesbaden 65173, GERMANY; Marc Duecking, Bundeskriminalamt, Forensic Science Institute, KT 13, Wiesbaden 65173, GERMANY; Peter Watzke, Bundeskriminalamt, Forensic Science Institute, KT 13, Wiesbaden 65173, GERMANY; and Peter Weis, Bundeskriminalamt, Forensic Science Institute, KT 13, Wiesbaden 65173, GERMANY*

After attending this presentation, attendees will understand basic principles concerning the application of Isotope Dilution-Inductively Coupled Plasma/Mass Spectrometry (ID-ICP/MS) as a method of ultra-precise analyses. Issues such as the required materials and the working procedure will be addressed.

This presentation will impact the forensic science community by raising awareness on the activity of the re-evaluation of the concentration values of Float Glass Standards (FGS) glasses as calibration material for forensic glass analysis by Laser Ablation (LA) ICP/MS.

Over the last two decades, LA-ICP/MS has been proven to be a reliable and powerful technique in forensic glass analysis, especially for the comparative analyses of questioned and control glass samples. Harmonized measurement parameters have been established over time, leading to methods commonly used by the majority of forensic laboratories employing LA-ICP/MS.¹

In order to improve the accuracy of the quantitative analysis of float glasses by LA-ICP/MS, two matrix-matched standards (*doped with 20 elements of high discrimination power*) were produced in 2002 as part of a Bundeskriminalamt (BKA) research project. These FGS resemble soda-lime glass composition, but vary in their concentration of doped elements by a factor of 5. For more than a decade, FGS1 and FGS2 have been in use by several laboratories serving as matrix-matched calibration standards for the quantitative analysis of float glasses.

Information values for the FGS, validated by different analytical techniques (Atomic Absorption Spectrophotometry (AAS), Inductively Coupled Plasma/Optical Emission Spectrometer (ICP/OES), ICP/MS, LA-ICP/MS, Scanning Electron Microscopy with Energy-Dispersive X-ray Spectroscopy (SEM/EDS), and X-Ray Fluorescence (XRF)) were published in 2005.¹ Due to the great capability of isotope dilution ICP/MS in offering results of highest analytical quality and as the most important reference method for elemental analysis, this study will demonstrate the use of Isotope Dilution-Inductively Coupled Plasma/Mass Spectrometry (ID-ICP/MS) for three elements (neodymium, hafnium, and lead) resulting in more accurate and more precise values.²

In ID-ICP/MS, a known amount of isotope-enriched (spike) material of the analyte element is added to a sample with known isotopic composition of the analyte element, but with unknown elemental content. This completely mixed isotope diluted sample (blend) contains a new isotope ratio of the analyte element, which directly reflects the analyte concentration in the sample.²

The determined isotope dilution values of neodymium, hafnium, and lead for the glasses FGS1 and FGS2 will be compared to already-published data for these glasses. As for these three elements, results of isotope dilution ICP/MS are in good accordance with the neodymium, hafnium, and lead of isotope dilution resulting in a higher precision (lower uncertainty values) of the information values of FGS1 and FGS2. Therefore, this work should serve as a first step for a wider re-evaluation of the concentration values for main, minor, and trace elements in the Float Glass Standards FGS1 and FGS2.

Particular issues regarding the homogeneity of the FGS1 and FGS2 will be presented. Previous analyses have shown that particular areas of the glass (rim) exhibit elevated concentration of Cerium (Ce) and Lanthanum (La). This has been caused by the material applied by the final cutting process of the glass.

B17 Rapid Identification of Designer Drugs With Nuclear Magnetic Resonance (NMR) Spectroscopy

*Faith Fowler**, 295 Irving Avenue, #4L, Brooklyn, NY 11237; and *Ling Huang, PhD*, Chemistry Dept, 151 Hofstra University, Hempstead, NY 11549

After attending this presentation, attendees will understand the principles of Nuclear Magnetic Resonance (NMR) spectroscopy and how it can be applied to the rapid characterization and identification of designer drugs. Attendees will also learn about the power of combining multiple NMR techniques, such as proton spectroscopy, Correlation Spectroscopy (COSY), Total Correlation Spectroscopy (TOCSY), and Diffusion Ordered Spectroscopy (DOSY) in the analysis of designer drug samples. TOCSY can provide information about long-range proton-proton interactions, allowing for accurate identification with extra 2D molecular “fingerprints” beyond COSY. DOSY has the potential to separate the components of a mixture based on their diffusion coefficients. Consequently, signals from solvents and other materials can be separated from synthetic cannabinoid signals without chromatographic separations.

This presentation will impact the forensic science community by introducing a simple but highly discriminatory NMR procedure that can be used to quickly identify a wide variety of designer drugs such as “Spice” (synthetic cannabinoids), “Molly” (phenethylamines), and “Bath Salts” (cathinones).

Designer drugs are a persistent problem for forensic laboratories. As the government bans synthetic cannabinoids, phenethylamines, and cathinones, those who produce these substances create new substances to maintain the legality of their business. The ever-changing nature of this market can be a burden to forensic laboratories that receive large amounts of seized materials containing unfamiliar substances.

The proposed methodology expands upon the laboratory’s previous work in which proton and COSY NMR methods were developed to quickly identify and quantify synthetic cannabinoids in herbal samples. The whole analytical process took less than one hour after cannabinoids were extracted from 50mg of herbal incense with an NMR solvent such as CDCl_3 . The same simple pre-NMR sample preparation technique is preserved to rapidly obtain NMR results. The current expansion includes incorporating more NMR techniques such as TOCSY and DOSY. TOCSY experiments were performed on herbal samples with previously known synthetic cannabinoids. These experiments revealed that signals coming from the alkyl region of the cannabinoid molecules can be elucidated further, as this is a region where signals tend to overlap or may be hard to assign with proton NMR and COSY. DOSY experiments with herbal samples successfully separated solvent and other materials from cannabinoid signals in samples that contain only one cannabinoid. Due to signal overlap, separation based on diffusion coefficient is extremely difficult in samples containing multiple cannabinoids. As of now, signals from two different cannabinoids cannot be separated efficiently using DOSY.

The original methodology is further expanded to include additional designer drugs typically found in “Molly” and “Bath Salt” mixtures. Eleven phenethylamine and cathinone standards were characterized using proton-NMR and COSY with similar parameters compared to the synthetic cannabinoid experiments, with the exception of D_2O as the NMR solvent. Potential signature peaks were identified that could be utilized to quickly identify the components of a street sample. Compared to the results from liquid chromatographic separation with Diode Array Detection (DAD) on the same standards, NMR proves to be a more reliable process at the identification because many of the substances are fairly similar, often isomers of each other, and therefore elute at similar times.

In conclusion, the addition of TOCSY and DOSY NMR methods can improve the discriminatory power of NMR for the identification of synthetic cannabinoids in herbal incense blends. The NMR parameters can also be successfully applied to other designer drugs. These methodologies could be valuable screening tools for backlog reduction, allowing analysts to quickly obtain “fingerprints” of the substance while preserving the original sample for further testing.

Designer Drugs, NMR, TOCSY

B18 Differentiation of Cosmetic Foundations Using Liquid Chromatography/Tandem Mass Spectrometry

Thomas A. Brettell, PhD, Cedar Crest College, 100 College Drive, Allentown, PA 18104; Thomas H. Pritchett, MS, 100 College Drive, Allentown, PA 18104; and Emily A. Myers, BS, 2133 Stoops Court, PO Box 602, North Apollo, PA 15673*

After attending this presentation, attendees will have a better understanding of how cosmetic foundation can be analyzed as a form of trace evidence.

This presentation will impact the forensic science community by providing a simple and sensitive Liquid Chromatography with Tandem Mass Spectrometry (LC/MS/MS) method to differentiate different cosmetic foundations through the analysis of specific preservatives.

Preservatives are natural or synthetic ingredients that are commonly added to products in order to prevent spoilage, including but not limited to microbial growth or undesirable chemical changes, ultimately extending the products' shelf life. Without the addition of preservatives, the foundation has the ability to easily become contaminated, leading to product degradation, and increasing the risk of irritation or infection. In the United States, the Food and Drug Administration (FDA) regulates the use of preservatives under the cosmetic provisions of the law and manufacturers to determine at what levels the preservatives are considered "safe" for consumer use. The most widely used preservatives in cosmetic products are parabens.

This study has developed an LC/MS/MS method for differentiating different brands of cosmetic foundations by observing the absence and/or presence of specific preservatives, including six different parabens. The analyte preservatives used in this study were methylparaben, ethylparaben, n-propylparaben, isopropylparaben, butylparaben, benzylparaben, tocopheryl acetate, and 3,5-di-tert-Butyl-4-Hydroxytoluene (BHT). The method is capable of separating and identifying all eight preservatives in less than seven minutes including the separation of n-propylparaben and isopropylparaben which has not been accomplished and reported prior to this method. LC/MS/MS data was acquired using an ABI® Sciex 3200 QTRAP® triple quadrupole mass spectrometer interfaced with a Shimadzu® LC system. The instrument utilized Electrospray Ionization (ESI) and all samples were run in positive-ion mode monitoring. Chromatography was performed on a 5.0cm x 3.0mm x 2.7µm Ultra® biphenyl column. The strong mobile phase used was 0.1% formic acid in 2-propanol and the weak mobile phase used was 0.1% formic acid in High-Performance Liquid Chromatography (HPLC) -grade methanol. A Shimadzu® SIL-20AC Prominence auto sampler injected 2.0µL of sample and the column oven temperature was set isothermally at 25°C throughout the run with a flow rate of 0.300µL/min. A retention time optimization study provided preeminent separation conditions.

Foundation samples were prepared by adding approximately 100mg of each foundation to 5mL of methanol:acetonitrile (1:1) and sonicating for ten minutes. After sonication, the solution was placed into centrifuge tubes and centrifuged for 5 minutes at 3,000rpm. After centrifugation, the supernatant was carefully removed using disposable pipettes and filtered using a 0.2µm Millipore® filter. One mL of the supernatant was added to a vial along with 60µL of the internal standard. Lastly, 2.0µL of sample was injected onto the LC column.

Separating and identifying the six parabens as well as the other preservatives proved to be simple and quick. The method is capable of identifying which preservatives are present in a cosmetic sample with a limit of detection of 0.5µg/mL. Twelve different brands of cosmetic foundations were tested and all were easily differentiated by analysis of the preservatives in the samples using the LC/MS/MS method.

Preservatives, Cosmetic Foundation, LC/MS/MS

B19 Latent Fingermarks Revelation on Human Skin With the Lumicyano™ One-Step Fluorescent Revelation Process

*Maxime Lemoine**, Unité de Taphonomie Médico-Légale (UTML), rue André Verhaeghe, Lille, Nord 59000, FRANCE; *Thomas Colard*, DDS, PhD, Institut de Médecine Légale, Place de Verdun, Lille, Nord 59045, FRANCE; *Yann Delannoy*, MD, Forensic Taphonomy Unit, Rue André Verhaeghe, Lille 59000, FRANCE; *Cosimo Prete*, Msc, Crime Scene Technology, 2b-21 Allée du Cercle, Villeneuve d'Ascq 59000, FRANCE; and *Valéry C. Hedouin*, MD, PhD, Iml-chu Lille, Rue Andre Verraeghe, Lille 59000, FRANCE

After attending this presentation, attendees will have an enhanced understanding of a new method of fingerprints revelation on human skin.

This presentation will impact the forensic science community by serving as a key aspect of crime scene investigation as it can augment traditional means of investigation with a fast latent fingerprint detection method on human skin.

To detect latent fingerprints on smooth surfaces like metals, plastic, glass, etc., the treatment with glues containing Cyanoacrylate Ester (CA), also known as super glue, is a commonly used technique worldwide. In fuming chambers, the CA is vaporized and polymerizes as a white residue on all surfaces of the possible fingerprint carrier. This makes every fingerprint easily detectable and fixes them at the same time. Additionally, the polymerized CA fixes all other possible biological traces on the carrier that could be of interest for subsequent genetic analysis (e.g., blood, saliva, or sperm stains). Even though this process is widely known, no such revelation method exists when considering human skin surfaces.

Lumicyano™ is a one-step fluorescent cyanoacrylate able to develop fingermarks on various surfaces. It appears much easier to use in a forensic laboratory than the other fluorescent cyanoacrylate described in the literature, especially as it has been designed for use under standard fumigation conditions (120°C, 80% humidity). It allows investigators to develop fingermarks with a quality equivalent or better compared to the conventional, non-fluorescent cyanoacrylate.

In this study, three donors (three males of different ages) were chosen for the intervariability of their fingerprint quality. Sebaceous and eccrine marks were deposited on four 10cm x 10cm human skin samples of the back. A 3x5 square grid was represented on each of the skin samples and donors were asked to let their fingers contact the samples for two seconds on each of the five squares of the corresponding line (i.e., line one for donor one, etc.). Between each contact, hands were washed and dried and donors were asked to wipe the wings of their noses.

Time and ageing conditions have an effect on cyanoacrylate fuming efficiency. To check the Lumicyano™ ability to detect fresh and old marks, three ageing times were chosen (i.e., immediately after deposition, one hour after, and one day after). Cyanoacrylate fuming with Lumicyano™ was then performed in a fuming cabinet MVC 5000 (2003 model version 6.2b). After being processed, each fingerprint was gathered and photographed under white light, then lit under ultraviolet light (312nm), and photos were taken within four hours of fumigation.

For each series, technicians were provided with an instruction sheet and were asked to assess fingerprints according to three evaluation criteria: (1) contrast (meaning the ability of the fingerprint ridges to part with the background); (2) ridge continuity (meaning the possibility of watching unbroken ridges and the ridges flow); and, (3) level of detail (meaning the possibility of watching second level (minutiae) and third level (pores and ridge edges)) details. Results were then compared to fingerprints deposited on microscope slides.

The detailed comparative examinations presented in this study show that Lumicyano™ makes it possible to accurately develop fingermarks on human skin with a high-quality contrast. The luminescent signal provided by the Lumicyano™ allows obtaining readily fluorescent marks; however, the signal is sometimes less intense than the one obtained on microscope slides, especially in the case of poorly developed fingermarks. Nevertheless, this study has shown that Lumicyano™ allows the development of fluorescent fingermarks on human skin for which other two-step sequences methods are often problematic.

Further studies are in progress to improve the fluorescence signal, either by modification of the fluorophore or by making several developments on one item without overdevelopment of the fingerprint.

Latent Fingermarks, Fluorescent Cyanoacrylate, Human Skin

B20 Characterization of Electrical Tapes by Laser Ablation-Inductively Coupled Plasma/Mass Spectrometry (LA-ICP/MS) and Scanning Electron Microscopy With Energy-Dispersive Spectroscopy (SEM/EDS)

Claudia Martinez, BSc, Florida International University, 11200 SW 8th Street, Miami, FL 33199; Tatiana Trejos, PhD, Florida International University, Chemistry Dept, 11200 SW 8th Street, University Park, OE 109, Miami, FL 33199; Yu Cheung, BSc, Florida International University, 11200 SW 8th Street, Miami, FL 33199; Melanie Perez, Florida International University, 11200 SW 8th Street, Miami, FL 33199; Andria H. Mehlretter, MSFS, FBI Laboratory, Chemistry Unit, 2501 Investigation Parkway, Quantico, VA 22135; and Jose R. Almirall, PhD, Florida International University, Dept of Chemistry, University Park, Miami, FL 33199*

After attending this presentation, attendees will better understand the versatility and utility of LA-ICP/MS for the characterization and comparison of tape evidence and its performance compared to SEM/EDS.

This presentation will impact the forensic science community by providing an assessment and validation of an LA-ICP/MS method for the forensic analysis of electrical tape evidence commonly found in murders, kidnappings, and improvised explosives, to mention a few. This technology has demonstrated its utility in other matrices such as glass, paint, soil, document examinations, and chemical taggants. The validation of this method for tape analysis will now expand the variety of forensic evidence that is currently characterized and analyzed by LA-ICP/MS, providing a more cost-effective solution that can be used across a large number of subdisciplines and materials, hence facilitating the incorporation of this useful tool into forensic laboratories.

Forensic examiners make use of chemical characterizations of both the organic and inorganic components in tapes to support other examinations including physical properties and even an apparent physical match. Current protocols used for electrical tape examinations may include the elemental analysis of backings and adhesives by SEM/EDS and/or micro X-ray fluorescence. Although these techniques have been shown to provide valuable elemental characterization of tapes, they have limited selectivity and sensitivity. The current study evaluated the forensic utility of LA-ICP/MS as an alternative method for the inorganic characterization of tape evidence.

The hypothesis of this research was that the superior sensitivity and selectivity of LA-ICP/MS methods could provide enhanced chemical characterization and improved discrimination between electrical tapes originating from different sources. To test that hypothesis, this study compared the performance of LA-ICP/MS to SEM/EDS data previously collected by another group on a collection set of 90 black electrical tapes. The overall discrimination for the 90 samples was found to be 93.8%, which was superior to the discrimination found using SEM/EDS (87.3%). Moreover, LA-ICP/MS detected a larger number of elements offering complementary information to the chemical characterization obtained by SEM/EDS. A second hypothesis was that the analytical performance provided by LA-ICP/MS was appropriate for the inherent chemical heterogeneity and the subsequent characterization of tape evidence. For this purpose, studies on the variation of the elemental composition within a roll were conducted for seven rolls. Each roll was split into six sections and each section was characterized in six replicates at different locations. Results demonstrated that the amount of material removed during analysis provided a representative characterization of the elemental composition of a number of tape rolls. Inter-roll variations were found to exceed intra-roll variations in all cases, making this technique viable as a comparison tool.

A set of 45 duplicate-control blind samples, each one originating from different locations of the same roll, were analyzed on different days and by different analysts to evaluate instrumental variations, inter-day variations, and false exclusion rates. A set of 100 electrical tapes originating from different sources was analyzed in four to six replicates to evaluate the false inclusion rates and the discrimination capability of the proposed method. False exclusion rates lower than 5% and false inclusion rates lower than 6% were observed for the selected collection sets, respectively. These results were evaluated to make informed decisions about sampling, chemical analysis, and interpretation of the data collected. A variety of statistical tools were evaluated to determine which one(s) are suitable to the particular sensitivity and precision level of the proposed method.

This work will also describe the optimization and examinations performed on electrical tapes using LA-ICP/MS to achieve ideal penetration into the tapes' backings and adhesives with minimal destruction to the evidence.

Electrical Tape, Trace Evidence, Elemental Analysis

B21 Body Fluid Identification by Mass Spectrometry From Sexual Assault Evidence

*Kevin M. Legg**, 2300 Stratford Avenue, Willow Grove, PA 19090; *Heather E. Mazzanti, MSFS*, 450 S Easton Road, Glenside, PA 19038; *Christian G. Westring, PhD*, 2300 Stratford Avenue, Willow Grove, PA 19090; and *Phillip Danielson, PhD*, Department of Biology, 2101 E Wesley Avenue, Lab 223, Denver, CO 80210

After attending this presentation, attendees will be aware of a novel workflow for screening of biological material originating from sexual assault kits through the use of targeted mass spectrometry.

This presentation will impact the forensic science community by illustrating how this work has the potential to significantly improve serological screening of forensic evidence. Not only will practitioners be able to obtain unambiguous test results for saliva and seminal fluid, but the multiplex design will eliminate the need to perform separate tests on an unknown stain. In short, the successful completion and implementation of this technology will provide a powerful tool for screening and prioritization of sexual assault-type samples for laboratory processing and criminal investigation.

While DNA profiling makes it possible to individualize biological stains, the accurate characterization of the biological material present can provide critical information to prioritize samples for subsequent microscopic and DNA analyses. Currently, the technologies used for the confirmation of seminal fluid and saliva (critical fluids for screening sexual assault evidence) are primarily based on antibody and enzyme activity-based assays.

Contrary to the marketing claims made by some commercial providers, the identification of seminal fluid and saliva by these methods is based on a presumptive indication of the presence of a body fluid. Positive results with non-target body fluids, false positives with non-biological materials, and antibody cross-reactivity with non-human sources have been well documented in the forensic literature.

Thus, it is recognized that there is clear value in developing alternative approaches that are both sensitive and accurate for the identification of human biological stains. To date, a proteomics-based analysis of human body fluid proteomes have identified multiple protein biomarkers for six forensically relevant body fluids — including seminal fluid and saliva. The specificity of each biomarker, the reliability with which it can be detected, and the degree of inter-individual variability in expression has already been demonstrated across a large sample population of human subjects.

These biomarkers have been incorporated into a targeted mass spectrometry assay for the identification of human seminal fluid and saliva. The work described here employs simulated sexual assault swabs in order to compare the sensitivities of the mass spectrometry approach relative to several commercial immunochromatographic tests for the detection of seminal fluid and saliva. To assess this, simulated sexual assault swabs were prepared by spotting varying quantities of semen and saliva onto blank semen-free vaginal swabs. Each dilution was assayed using commercial immunochromatographic systems for saliva (RSID™ Saliva) and semen (RSID™ Semen and Abacus Diagnostics® ABACard® p30) as well as by targeted mass spectrometry on a triple quadrupole mass spectrometer. All targeted biomarkers for both seminal fluid and saliva were reliably detected (based on response ratios, retention times, peak shape, and symmetry as compared to a known positive control) at all dilution levels by the mass spectrometry method. Conversely, several immunochromatographic systems produced erroneous weak positive results due to the hook effect while yielding only weakly positive results at the lowest quantities of spotted body fluid.

Based on these results, the mass spectrometry-based approach offers a superior detection platform while consuming less evidentiary material. In addition, the mass spectrometry-based approach is well suited for simultaneous fluid identification, is compatible with batch analyses in multi-well plate formats, and offers automated data processing and reporting of true confirmatory results.

Serology, Mass Spectrometry, Proteomics

B22 The Occurrence of Forcibly Removed Hairs in Combs and Hair Brushes

Kimberly Sutton, BS, Georgia Bureau of Investigation, 3121 Panthersville Road, Decatur, GA 30034; Anne Kisler-Rao, MS, 3121 Panthersville Road, Decatur, GA 30034; and Melissa Lynn Quartarone, BS, Georgia Bureau of Investigation, 3121 Panthersville Road, Decatur, GA 30034*

After attending this presentation, attendees will learn about the occurrence of forcibly removed hairs found in combs and hair brushes.

This presentation will impact the forensic science community by accounting for one alternate explanation as to why forcibly removed hairs could be found at a crime scene.

A hair examiner is occasionally asked whether or not a hair has been forcibly removed, as indicated by a hair possessing an anagen root. In one particular instance, a hair examiner was asked during testimony in a child abuse case if a large group of hairs possessing anagen roots was pulled out or could have come from brushing. This study was designed to observe the growth stages of hairs present in hair brushes and combs to determine whether or not it is likely for a large group of forcibly removed hairs to have come from a person simply brushing their hair.

Subjects were asked to clean out their hair brushes or combs prior to obtaining the sample for this study. They were then asked to comb or brush their hair as normal and collect the comb or brush in a ziplock bag. The hairs were then removed from the comb or brush, mounted on slides with permount, and proximal ends were categorized into one of three groups: anagen, catagen/telogen, or broken.

For each individual, a number of factors were recorded to include race, sex, age (or approximate age when the subject would not reveal their age), and type of comb or hair brush used. Combs and brushes were categorized into seven different general types.

Thirty-nine individuals participated in this study and a total of 1,216 hairs were examined from these individuals. Of these hairs, 26 had anagen roots (2%), 306 were broken at the proximal end (25%), and 884 had catagen/telogen roots (73%). Thirty-one of the samples examined did not contain any anagen roots. The highest number (and percentage) of anagen roots found in any one sample was six out of 26 hairs (23%) from a 13-year-old White male using a comb.

The three Black samples examined are of note, as they contained predominantly broken hairs: 61 out of 73 hairs (84%), 51 out of 68 hairs (75%), and 74 out of 137 hairs (54%). High numbers of broken proximal ends were also seen in a White female with heavily treated hair: 21 out of 22 hairs (95%) and a 6-year-old White female: 36 out of 53 hairs (68%). The Black samples and the color-treated White sample did not contain any anagen roots, while the 6-year-old sample contained four anagen roots (8%).

The results of this study show that it is not common to find large numbers of anagen roots on hairs recovered from brushes or combs after a single brushing. This finding should be considered when evaluating possible explanations for the occurrence of forcibly removed hairs.

Hair, Roots, Force

B23 Utilization of Commercial Portable Instruments for Screening Hand Swabs for the Presence of Firearms Discharge Residue (FDR): Validation of Commercial IMS and XRF Instruments to Screen for FDR

James Stewart, BS, West Virginia University, 1600 University Avenue, 208 Oglebay Hall, Box 6121, Morgantown, WV 26506-6121; Katelyn Bustin, BS, West Virginia University, Forensic Chemistry, 1600 University Avenue, 208 Oglebay Hall, Box 6121, Morgantown, WV 26506-6121; Ryan Dross, BS, West Virginia University, Forensic Chemistry, 1600 University Avenue, 208 Oglebay Hall, Box 6121, Morgantown, WV 26506-6121; Brittany Yeager, BS, 277 Carr Avenue, Clarksburg, WV 26301; and Suzanne Bell, PhD, West Virginia University, Oglebay Hall, Rm 208, 1600 University Avenue, Morgantown, WV 26506-6121*

After attending this presentation, attendees will understand the potential merit of screening for FDR using commercially available portable instruments and hand swabs.

This presentation will impact the forensic science community by providing method validation results and figures of merit for the portable instruments used to screen hand swabs for the presence of FDR.

Gunshot Residue (GSR) as traditionally defined consists of particulates containing lead, antimony, and barium (principally) that are formed from primer components that are vaporized during the firing of a weapon. The primary analytical technique used to characterize GSR is Scanning Electron Microscopy (SEM) coupled to X-ray spectroscopy. While conceptually and analytically sound, the drawbacks to this procedure are known and include loss due to secondary transfer and the challenge of interpretation of results.¹⁻⁴ Consequently, the forensic analysis of samples collected from the skin of potential shooters is no longer commonplace.

This practice is regrettable given that the firing of a weapon yields a wealth of useful physical and chemical evidence. GSR is only one type of evidence produced when a weapon is discharged; organic compounds are also produced and encompass residual energetics, stabilizers and additives, and combustion products. This chemical residue is referred to as Organic Gunshot Residue (OGSR) and has been addressed in recent literature reports.^{2,5-7} The organic and inorganic components combined are referred to as Firearms Discharge Residue (FDR). The focus of this study is the description of the validation of three Ion Mobility Spectrometers (IMS) and one X-Ray Fluorescence (XRF) spectrometer to screen hand swab samples for presence of FDR. A significant effort was directed toward identifying the ideal swabbing media and protocols that yielded samples compatible with all instruments as well as with Scanning Electron Microscopy with Energy-Dispersive X-ray Spectroscopy (SEM/EDS) for confirmation purposes; these results will be summarized. Overall, muslin and Nomex[®] substrates were found to be optimal and, using high-vacuum SEM, it is possible to identify GSR particulates on these swabs as well.

Method validation followed acceptable international standards (**International Organization for Standardization (ISO)** and Scientific Working Groups (SWGs)) and the relevant figures of merit will be presented for each instrument. Instruments were used in alarm mode (present/absent) with thresholds rigorously determined using signal/noise measurements and determination of limits of detection for several organic compounds. Repeatability, reproducibility, ruggedness, and robustness were characterized and daily performance was monitored using control charts. For the OGSR, diphenylamine, dimethyl phthalate, ethyl centralite, and methyl centralite were the primary target compounds and for XRF, lead was the focus. Sample stability and holding time data will be presented. It was determined that samples stored at -20°C in darkness were stable for at least six months. Because only portions of the swab surfaces were subject to thermal desorption for IMS sample introduction, sufficient sample remained for further analysis. Results showed that overall, the best performance was achieved using a Smith's Detection Sabre 4000 portable IMS; the limitation to this instrument was the inability to analyze samples that ionize in the negative mode such as nitroglycerin and other compounds that yield a nitrate response.

FDR, IMS, Validation

B24 The Development of Paper Microfluidic Devices for the Presumptive Determination of Seized Drugs

Jashaun Bottoms, Tuskegee University, 1200 W Montgomery Road, Tuskegee, AL 36088; Bruce R. McCord, PhD, Florida International University, Dept of Chemistry, University Park, Miami, FL 33199; and Ling Wang, Florida International University, CP-304 11200 SW 8th Street, Miami, FL 33199*

The goal of this presentation is to demonstrate the application of paper microfluidic devices and colorimetric tests in the presumptive determination of seized drugs. Information will be presented on the design of paper-based multiplexed colorimetric detection, how to optimize detection of drugs on paper microfluidic devices, and will demonstrate a variety of applications of the multichannel paper chips.

This presentation will impact the forensic science community by demonstrating the application of paper microfluidic devices as a useful tool for detecting seized drugs in solution. The new method is rapid, inexpensive, and applicable to a variety of seized drugs.

Currently, a wide variety of illicit drugs can be screened using presumptive colorimetric test solutions. These colorimetric reagents have been used to detect seized drugs for many years; however, the storage of these solutions not only occupies space but also involves the use of toxic and corrosive chemicals. Use of these tests in the field can be awkward and may not always be possible in challenging environments. This study has been working on an alternative platform for colorimetric detection based on paper microfluidic devices. Using wax printing and chromatographic paper, four lane chips have been created that adapt the colorimetric reagents to a ready-to-use format. Sample and solvent are applied to the paper just prior to analysis and each lane performs a different test. These devices can be used at crime scenes, in laboratories, and at any other location where seized drugs need identification. The preparation of paper microfluidic devices is simple and inexpensive and they can be conveniently stored for later use.

The paper microfluidic devices are designed as a four-channel multiplexed system. Preparation of the devices requires a wax-ink printer, chromatography paper, and colorimetric reagents. A series of hydrophilic channels are created and outlined in wax on the paper using the wax-ink printer and a laminator. Next, a set of different colorimetric reagents are spotted in each channel to create the detection zone. Drugs dissolved in solutions are then transferred to the chips where they move to the detection zone via capillary action. Sequences of different reagents can be applied to each channel to produce a series of reactions and the color changes finally appear at the end of each channel. The entire process generally takes less than five minutes. Because each drug can produce specific color changes in different channels, it becomes possible to presumptively determine the type of drugs in solutions.

One important aspect of this project is the selection of potential reagents for the device. Traditional colorimetric reagents, such as the Mandeline and Frohdes reagents, use concentrated sulfuric acids. Acids such as sulfuric acid and nitric acid can burn and digest chromatographic paper. As a result, a variety of chemical tests have been performed to modify these reagents to make them more compatible with the paper-based format. For example, potassium manganate (VII), copper (II) sulfate, and iron (III) oxide have been utilized as alternative reagents. The adjusted colorimetric reagents produce specific color changes for seized drugs on paper microfluidic devices. Procedures have been developed for the detection of cocaine, ketamine, codeine, and ephedrine and have been tested against a variety of potential interferences.

Overall, the use of paper microfluidic devices permits the development of rapid, easily stored test beds for a variety of seized drugs. They present a quick presumptive tool for samples which can be used in the field, prior to confirmatory laboratory analysis.

Paper Microfluidic Devices, Seized Drugs, Colorimetric Test

B25 Utilization of Commercial Portable Instruments for Screening Hand Swabs for the Presence of Firearms Discharge Residue (FDR): Collection Efficiency Using Commercial and In-House Media

James Stewart, BS, West Virginia University, 1600 University Avenue, 208 Oglebay Hall, Box 6121, Morgantown, WV 26506-6121; Katelyn Bustin, BS, West Virginia University, Forensic Chemistry, 1600 University Avenue, 208 Oglebay Hall, Box 6121, Morgantown, WV 26506-6121; Brittany Yeager, BS, 277 Carr Avenue, Clarksburg, WV 26301; Suzanne Bell, PhD, West Virginia University, Oglebay Hall, Rm 208, 1600 University Avenue, Morgantown, WV 26506-6121; and Ryan Dross, BS, West Virginia University, Forensic Chemistry, 1600 University Avenue, 208 Oglebay Hall, Box 6121, Morgantown, WV 26506-6121*

After attending this presentation, attendees will understand what types of hand-swabbing materials are available for collection of FDR from the hands of potential shooters for subsequent analysis using a variety of analytical instruments.

The presentation will impact the forensic science community by providing data on methodology and efficacy of hand swabbing for the detection of FDR.

Gunshot Residue (GSR) consists of particulates containing lead, antimony, and barium (principally) that are formed from primer components that are vaporized during the firing of a weapon. The primary analytical technique used to characterize GSR is Scanning Electron Microscopy (SEM) coupled to X-ray spectroscopy. While conceptually and analytically sound, the drawbacks to this procedure are known and include loss due to secondary transfer and the challenge of interpretation of results.¹⁻⁴ Consequently, the forensic analysis of samples collected from the skin of potential shooters is no longer commonplace.

This is regrettable given that the firing of a weapon yields a wealth of useful physical and chemical evidence. GSR is only one type of physical evidence available; organic compounds are also produced when a weapon is discharged. This chemical residue is referred to as Organic Gunshot Residue (OGSR) which has been addressed in recent literature reports.^{2,5-7} The organic and inorganic components combined are referred to as FDR. The focus of this study is to discuss research and validation studies undertaken using a variety of hand swabbing methods with the goal of using the collected samples in both presumptive and confirmatory analyses for organic and inorganic compounds.

The criteria for selection of media were: (1) wettability using isopropanol; (2) stability under thermal desorption conditions; (3) compatibility with several portable instruments for presumptive testing (X-ray fluorescence and ion mobility spectrometry); (4) extractability; and, (5) compatibility with Scanning Electron Microscopy with Energy-Dispersive X-ray Spectroscopy (SEM/EDS) methodology. Materials analyzed including clean room wipes, a raw fabric of Kevlar[®]/Nomex[®], and commercially prepared Nomex[®] and muslin swabs. The combination of these materials and isopropanol as the wetting agent yields a simple, non-invasive sampling technique that has been approved by the West Virginia University Institutional Review Board (WVU IRB). The advantages and disadvantages of each media will be presented in terms of recovery efficiency from a skin surrogate, instrumental compatibility and performance, extractability, and stability of samples under typical storage conditions.

Hand Swabbing, GSR, IMS

B26 High-Resolution MS/MS Spectral Library for Synthetic Cannabinoids by Direct Analysis in Real-Time Quadrupole Time-of-Flight Mass Spectrometry

Tyler Torbet, 1551 SW 104th Pkwy, Apt 115, Miami, FL 33174; and Jose R. Almirall, PhD, Florida International University, Dept of Chemistry, University Park, Miami, FL 33199*

After attending this presentation, attendees will learn how Direct Analysis in Real-Time Quadrupole Time-of-Flight Mass Spectrometry (DART[®]-Q-TOF/MS) can be applied for the identification of synthetic cannabinoids and the usefulness of a spectral library for these compounds. This presentation will highlight the advantages and limitations of DART[®]-Q-TOF/MS over traditional Gas Chromatography/Mass Spectrometry (GC/MS) and Liquid Chromatography/Mass Spectrometry (LC/MS) drug analysis as well as show the development of a spectral library for synthetic cannabinoids using this technique.

This presentation will impact the forensic science community by demonstrating how DART[®]-Q-TOF/MS can be used to rapidly produce high-resolution data for synthetic cannabinoids that can then be compiled into a spectral library to allow for faster identification of these compounds in seized products.

Abuse of synthetic cannabinoids has increased dramatically since the first report in Europe in 2004 and first detection in the United States in 2008. Typically sprayed on plant leaves, flowers, or stems, and packaged as herbal incense mixtures under the names “Spice” and “K2” among others, these compounds are marketed as “legal highs.” Although legislation has been passed such as the Synthetic Drug Abuse Prevention Act in 2012, the number of synthetic cannabinoids has continued to increase, many of which are analogs of other compounds developed to circumvent this legislation. This complicates identification of synthetic cannabinoids due to the high level of similarities in structure. DART[®] is an ambient ionization technique that requires little-to-no sample preparation and utilizes lower energy ionization than electron ionization, typically used with GC/MS, meaning less fragmentation and the observance of molecular ions. The DART[®] and Q-TOF/MS parameters were optimized and are reported. When paired with a mass spectrometer, DART[®] allows for rapid analysis and identification as the sample only needs to be introduced into the gas stream for a few seconds in order to produce spectra. Over 100 synthetic cannabinoid standards were analyzed by DART[®]-Q-TOF using the optimized method to generate molecular ions and fragmented spectra and searched on an existing database of Electrospray Ionization (ESI) -generated spectral database with excellent results. The DART[®]-Q-TOF method is a fast and effective tool that provides rapid analysis and identification of seized synthetic cannabinoid products.

This presentation will describe the capabilities of DART[®]-Q-TOF to quickly and accurately identify synthetic cannabinoids and their analogs while also describing the spectral library development. DART[®]-Q-TOF provides an alternative technique for the more commonly used GC/MS and LC/MS which are slower, increasing the amount of analysis time required in drug seizure cases.

Direct Analysis in Real Time, Synthetic Cannabinoids, Spectral Library

B27 Nanoparticle-Assisted Laser Desorption Ionization of Drugs

Rachel West, BSc, Flinders University, GPO Box 2100, Adelaide, South Australia 5001, AUSTRALIA; Stewart Walker, PhD, Flinders University, Phys Sci, For & Analytic Chem, GPO Box 2100, Rm 304, Adelaide, SA 5001, AUSTRALIA; and Paul Kirkbride, PhD, Flinders University, GPO Box 2100, Adelaide 5001, AUSTRALIA*

After attending this presentation, attendees will better understand the operation and capabilities of Laser Desorption/Ionization (LDI) mass spectrometry, as well as being aware of a broader range of possible analytes and applications.

This presentation will impact the forensic science community by exposing them to the capabilities of a technique traditionally used for biological purposes, expanding its use to forensic samples such as drugs.

Matrix-Assisted Laser Desorption Ionization-Mass Spectrometry (MALDI-MS) is a technique commonly used for the analysis of large biological molecules. Matrices are added to the system as a means of aiding in desorption and ionization of relatively stable analytes, transferring the required energy from the laser. As a soft ionization technique, these thermally unstable samples are able to be analyzed via MS with minimal fragmentation. This means more molecular ions are produced and analysis of results is simpler. Other advantages of this technique include minimal sample preparation as well as high selectivity and sensitivity. Having MALDI available for the analysis of drugs would be highly useful; however, the low mass nature of the drugs results in matrix interference due to peaks from the matrix itself being in the low mass region, making analysis more difficult. This has led to the use of a variety of alternative matrices and surfaces to facilitate the analysis of low mass entities. One of these alternatives is nanoparticles, which absorb the heat from the laser and pass this energy on. A range of different nanoparticles have been used in the analysis of peptides and other biological analytes.

This research uses nanoparticles as an alternative matrix in Laser Desorption Ionization-Mass Spectrometry (LDI-MS) to analyze a range of licit and illicit drugs in liquid and solid forms and from soaked fibers in the low mass (less than 400 Dalton) range.

In this project, gold and silicon nanoparticles were used, either mixed or layered with the drug of interest. The drug samples examined in this manner included opiates, such as codeine and morphine, and amphetamines including methamphetamine and other illicit drugs. These samples were analyzed at concentrations of approximately 1mg/mL. Samples were analyzed both directly on the MALDI plate and from drugs on paper samples mounted to the MALDI plate. Fibers from the loaded paper were removed and mounted on tapes of varying conductivity. Analysis took place in low mass, positive, reflectron mode using a 337nm N₂ laser. The laser strength required for analysis decreased from 100% without assisting materials to 50% or less when analyzed with small amounts of nanoparticles.

Nanoparticles have been previously found to be a viable matrix alternative for biological samples. The results from this study provide insight into the possibility of using these same materials for rapid and unequivocal drug analysis as well. Investigations continue into the analysis of other materials such as inks, paints, bodily fluids, energetic materials, and other compounds of forensic interest using this technique.

LDI, Drugs, Nanoparticles

B28 Exploration of the Electrochemical Enhancement of Latent Fingerprints

David Cunningham, PhD*, 5142 NSB, 521 Lancaster Avenue, Richmond, KY 40475; Connor T. Smith, 1729 Woodbluff Drive, Powell, OH 43065; Courtney N. Miller, Dept of Chemistry, 4142 New Science Bldg, 521 Lancaster Avenue, Richmond, KY 40475; and Taylor R. Baldwin, Dept of Chemistry, 4142 New Science Bldg, 521 Lancaster Avenue, Richmond, KY 40475

After attending this presentation, attendees will better understand the materials and processes involved in electrochemically depositing polymers onto latent fingerprints on metal surfaces to enhance their visibility. Deposition of intensely colored electrically conducting polymer in the valleys of the fingermarks is shown to result in a reverse image.

This presentation will impact the forensic science community by demonstrating the ability of select monomers, solvents, and electrochemical conditions to obtain excellent enhancement, including third-level detail of sweat pores, on a variety of metallic surfaces (doorknobs, spoons, coffee mugs, etc.). Exploratory studies also uncovered limitations of the method for base metals oxidized at potentials lower than the organic monomer.

While enhancement of latent fingerprints is well-established, significant challenges still exist. Among these is imaging prints on metallic surfaces including ammunition casings. Superglue fuming is widely used, partially due to the multiplicative effect of the polymerization reaction to produce a large amount of material from a smaller amount of fingerprint residue; however, cyanoacrylate is fairly clear in color and provides relatively poor contrast on metal surfaces. Several studies have suggested that oxidation of organic monomers to form intensely colored, electrically conducting polymers may be a viable approach to improving the poor success rate of enhancement on metal surfaces.¹⁻³ The present work was undertaken to systematically study the effect of the choice of organic monomer and solvent, as well as study controlled current and controlled potential systems. The controlled current studies were thought to allow the best repeatability of the amount of polymer deposited. The controlled potential system is most amenable to translation to a hand-held battery device for field use. Three electrode laboratory-based systems were used to understand important parameters including the oxidation of metal specimens and the effect of changing the monomer concentration. Two electrode systems were evaluated with an electrochemical potentiostat and the results used to design and test a portable battery-based system.

Initial screening results of five organic monomers (thiophene, 3-methyl thiophene, 3,4-Ethylenedioxythiophene (EDOT), pyrrole, and aniline) showed that the best enhancement was obtained with EDOT. Screening of five solvents of various polarities showed that better enhancement was obtained in more polar solvents, presumably since non-polar solvents dissolve the sebaceous fingerprint residue (fatty acids, wax esters, squalene, cholesterol, etc.) to a greater extent. Controlled current studies showed that charge densities in the range of 275-375 coulombs per square centimeter applied over a period of 20 seconds generally resulted in sufficient polymer to enhance the image so that it was judged suitable for identification; that is, either a three or four on the Bandy scale.⁴ The average thickness of the polymer is estimated as 0.23-0.30 micrometers based on 50% area coverage and 2.7 electrons per monomer unit polymerized. Additional controlled current studies (chronopotentiometry) demonstrated that progressively lower potentials were reached as the concentration of EDOT monomer was increased. Lower potentials reduce the amount of undesired side-reactions (oxidation of the metal substrate and oxidation of the solvent). At an EDOT concentration of 177mM, the potential generally remained below approximately 1.4 volts (vs. Ag/AgCl) at the optimal charge densities previously noted. In a two-electrode system, the optimal charge densities resulted in a voltage drop close to 3.4 volts across the cell.

Two electrode cells were constructed using 8mm-thick ethyl vinyl acetate foam from a craft shop sealed with silicon and applied over the latent fingerprint using double-sided duct tape and a stainless steel plate as a counter electrode. Various sizes of foam were easily constructed to conform to irregular shaped objects (doorknobs, spoons, coffee mugs). A typical cell with an area of 5.4 cm² required 4.2mL of EDOT solution. When the print was overdeveloped by deposition of excess polymer, application of tape was successful in improving the Brady score. Photography of the print on irregular metal objects was difficult, so various tapes were evaluated to identify if they could lift the polymer. In an evaluation of 12 brands of tape, D-SQUAME[®] performed the best.

In conclusion, significant fundamental work has been performed to identify materials and conditions for the formation of intensely colored conducting polymers to enhance latent fingerprints on metal. Good third-level detail prints have been obtained using short treatments with an easily constructed hand-held battery device.

Fingerprint, Tape Lift, Latent Fingerprint

B29 Effect of Reusing Swipe Materials for Particle Collection

Jessica L. Staymates, MFS*, 100 Bureau Drive, Mail Stop 8371, Gaithersburg, MD 20899; and Matthew E. Staymates, MS, National Institute of Standards and Technology, 100 Bureau Drive, Mail Stop 8371, Gaithersburg, MD 20899

The goal of this presentation is to investigate the number of times a collection wipe can be used before the Particle Collection Efficiency (PCE) decreases or the Ion Mobility Spectrometry (IMS) response is negatively affected. Trace collection is an important part of forensic work and knowing the effects of heat and age of the collection media can help in understanding optimal methods for trace collection.

This presentation will impact the forensic science community by offering a different perspective on swipe-based sampling media and how they can be reused multiple times.

When trace evidence is collected via wipe sampling, the collection material is rarely reused after it is analyzed; however, in the trace contraband detection community, it is sometimes common practice to reuse sampling media several times, especially when no contraband material is previously detected from it. The number of times a wipe can be used before it gets too dirty or the PCE becomes too poor for it to be useful for IMS-based trace detection is currently unknown within the trace detection community. There have been various suggestions, such as using a wipe until it is visibly dirty or discarding it after 25 uses. But there is a need for a method that measures the collection efficiency performance of a wipe material as a function of swipe use or age. The primary purpose of this study is to investigate the number of times a collection wipe can be used before the PCE decreases or the IMS response is negatively affected.

In order to “age” the wipe in a quick and repeatable fashion, a wipe-aging device was fabricated. The setup includes using a movable platen with an automated wand head, where three wipes can be attached at an ideal angle for swiping the “sweet spot” of the wipe. Air pressure is used to force the wand onto a surface and swipe with a repeatable distance and velocity. The air pressure was adjusted such that the downward force exerted by the wipe material was seven Newtons. In an earlier study, this force was found to be the average force a user would apply to a surface when asked to use “firm” force.¹ A variety of materials can be placed on the platen under the wand head to be swiped, such as canvas, vinyl, or cardboard. A robotic arm moves the collection wipe to a thermal desorber where it is heated for seven seconds (the same as a typical IMS analysis cycle), and cools for ten seconds before returning to the platen for the next swiping cycle.

To date, two types of wipes (Teflon[®]-coated fiberglass and Nomex[®]) have been aged by swiping them over various surfaces, including canvas and dirty cardboard, which represent materials that are likely to be swiped in a screening environment. They were swiped between 10 and 1,000 times, then PCEs were determined using previously discussed methods.² Next, known masses of explosives were inkjet-printed on the aged wipes to investigate whether the aging had an effect on IMS response. Finally, SEM images were captured to reveal and compare possible surface degradation of the wipes on a microscale level. Results will be discussed during the presentation.

It is understood that simply aging a wipe by swiping it across a surface does not capture all of the variables and environmental contaminants, a wider variety of surfaces, and contact with other materials such as disposable gloves can influence realistic aging of wipe materials in an operational setting. This experiment should help answer just a piece of the much larger puzzle that is the effect of wipe age as a function of wipe performance.

Trace Detection, Ion Mobility Spectrometry, Particle Collection

B30 Development of Paper Microfluidic Devices for the Detection of Organic and Inorganic Gunshot Residue

Kathryn R. Chabaud, BS, Florida International University, 11200 SW 8th Street, Miami, FL 33199; and Bruce R. McCord, PhD, Florida International University, Dept of Chemistry, University Park, Miami, FL 33199*

After attending this presentation, attendees will better understand current research on the development of paper microfluidic devices as a simple and inexpensive alternative to existing presumptive tests for Gunshot Residue (GSR). Minimal training is required to operate these devices and they are ideal for use in the field by military and law enforcement entities. Attendees will also gain a basic understanding of the analysis of lead-based and lead-free ammunition.

This presentation will impact the forensic science community by providing insight into the possibility of inexpensive, user-friendly, presumptive testing devices for GSR.

Colorimetric tests implemented on paper microfluidic devices permits residue from both inorganic and organic GSR to be detected in the field. Paper microfluidic devices are typically prepared from chromatographic paper creating hydrophilic channels through the use of wax printing and lamination at elevated temperatures. Capillary action is then used to mobilize liquids containing dissolved analytes through the wax ink channels of the device. Colorimetric reagents are placed at the terminal end of each channel for detection of the individual analytes. These devices were initially designed for application in medicinal and disease testing in remote areas where the lack of refrigeration limits the ability to store expensive reagents. Because reagents are dried on the device prior to use, shelf lives are increased when compared to liquid reagents. Various forensic applications of this technology have been explored. In this project, a paper microfluidic chip has been developed that involves presumptive, colorimetric tests for multiple different compounds contained in GSRs. Colorimetric tests have been designed for a variety of components in GSR. These tests were first prepared in solution and then optimized for use on paper.

GSR consists of organic and inorganic components that are left behind following the discharge of a firearm. Results are typically detected by atomic spectroscopy, mass spectrometry, or Scanning Electron Microscopy with Energy-Dispersive X-ray Spectroscopy (SEM/EDX) in the laboratory. Paper microfluidic devices have thus been developed for lead, barium, antimony, manganese, and zinc. Lead is detected via potassium iodide as well as through the use of a buffered mixture of sodium rhodizonate, which yields a yellow color and a pink color, respectively, upon reaction. Barium is also detected via the sodium rhodizonate mixture, yielding an orange color upon reaction. Antimony is confirmed via sodium sulfide which yields an orange/brown color upon reaction. Manganese is detected via potassium periodate which yields a brown color upon reaction. Lastly, zinc is detected with dithizone which yields a bright pink/purple color upon reaction. Work is also underway on a similar device to detect organic GSR including organic nitrates, nitrate esters, and diphenylamine.

This device, when optimized for reproducibility, stability, and sensitivity, should prove useful in the analysis of GSR, as the chip is not much larger than a postage stamp and minimal time is needed to produce results. The ultimate goal of the project is to design and test a set of these devices for the presumptive detection of lead-based and lead-free GSR in the field.

Gunshot Residue, Paper Microfluidics, Smokeless Powder

B31 New Psychoactive Substances Abused in South Korea: Drug Monitoring on the Seized Materials by National Forensic Service From 2009 to April 2014

Jaesin Lee, DPharm, National Forensic Service, 10 Ipchoon-ro, Wonju-si, Gangwon-do 220-170, SOUTH KOREA; Meejung Park, National Forensic Service, Narcotic Analysis Division, 139 Jiyangno, Yangcheon-gu, Seoul 158-707, SOUTH KOREA; Sanggil Choe, 139 Jiyangno Yangcheongu, Seoul, SOUTH KOREA; and Eunmi Kim, PhD, Busan Institute, National Forensic Service, 50 Geumoh-ro Mulgeum-eup Gyeongsangnam-do, Yangsan, SOUTH KOREA*

After attending this presentation, attendees will be informed about the recent trends of New Psychoactive Substances (NPS) seized during drug trafficking in South Korea.

This presentation will impact the forensic science community by providing information about the regional NPS trends in South Korea. International cooperation and information-sharing would be necessary to efficiently regulate the NPSs without a balloon effect.

Recent increases in the use of NPS have become a remarkable worldwide trend. These NPS are traded as “a legal high,” “herbal incense,” or “research chemicals.” Some of the NPS imported to South Korea were first interdicted by customs, while others have been seized by the police agency and the prosecutor’s office during drug trafficking. The National Forensic Service (NFS) identifies psychoactive substances seized mainly by the police agency and part of the prosecutor’s office; this collection may reflect the regional status of NPS abuse in South Korea.

According to drug statistics from the NFS, from 2009 to April 2014, the most frequently identified NPSs were synthetic cannabinoids (38 species) and synthetic cathinones (16 species). Recent trends in synthetic cannabinoids may be summarized as an increase in halogenated derivatives and new substances, including UR-144 and A-836,339, developed as analgesics by Abbot™ Laboratories. The N-pentyl fluorinated analog of UR-144 (XLR-11) has become the most frequently found synthetic cannabinoid in 2013 since its first appearance in 2012, whereas abuse of A-836,339 analogs has been little reported despite its abuse potential. Until early 2011, nicotine was the most frequently found active co-ingredient in synthetic cannabinoids; however, various psychoactive substances such as Δ^9 -tetrahydrocannabinol, α -PBP, α -PVT, and 5-MeO-DALT have often been found as co-ingredients in herbal highs since late 2011. On the other hand, increase of phenethylamine derivatives, including synthetic cathinones and amphetamine analogs, has recently become a new trend. It might be induced by the regional and global regulation on the herbal highs containing synthetic cannabinoids. The phenethylamine derivatives have been found in various types of materials including herbal incenses or dietary supplements.

Trade and abuse of NPS are highly restricted in South Korea by the Narcotics Control Act, which includes the temporary drug designation act and regulation on the analogs of major NPS. The numbers of chemical species and abuse cases of NPS have increased rapidly since 2010, and the Korean Food and Drug Administration (KFDA) added analogs of major NPS to the list of narcotics controlled by law in February 2011 based on the Canadian analog system; however, new compounds have continuously appeared. As a result, the KFDA applied a temporary drug designation act in June 2011 in order to reduce the interval required to legislate the drug regulation act; however, evolution of synthetic cannabinoids has become much faster than before. The most efficient ways to regulate the NPSs may include a rapid legislation system and extensive regulations of the analogs of possible abuse. For these reasons, regulatory systems should be improved continuously to cope with the endless evolution of NPS.

New Psychoactive Substance, Trend, South Korea

B32 Gunshot Residue on Evidence Packaging

*Mustapha Zein**, 2323 McCue Road, Apt 2702, Houston, TX 77056; *Kristina M. McNerney, BS*, 100 College Drive, Box 281, Allentown, PA 18104; *Jason L. Schroeder, MS, MBA*, Harris County Institute of Forensic Science, 1885 Old Spanish Trail, Houston, TX 77054; *William M. Davis, PhD*, 1885 Old Spanish Trail, Houston, TX 77573; and *Roger Kahn, PhD*, Harris County Institute of Forensic Science, 1885 Old Spanish Trail, Houston, TX 77054

After attending this presentation, attendees will better understand a source of Gunshot Residue (GSR) contamination and methods to minimize GSR contamination prior to analysis.

This presentation will impact the forensic science community by raising the awareness of law enforcement personnel, evidence technicians, and analysts to GSR packaging contamination so that personnel handling GSR-evidence packaging can take steps to prevent it from affecting GSR analyses.

GSR analysis is a valuable tool commonly used in forensic science to associate a suspect with the discharge of a firearm. Associations may result from firing a weapon, being in close proximity to a discharge, handling a weapon or fired cartridge, or handling some other surface bearing GSR. The presence of GSR particles does not prove that a person fired a weapon, but in a criminal investigation it can place an individual in the proximity of the firing of a weapon. As few as three GSR particles are sufficient to provide an association.

GSR particles can contaminate a surface by unintended transfer during collection. Since areas frequented by law enforcement personnel are known to contain GSR, effective efforts must be made throughout the evidence collection process to reduce the possibility of contamination. Proper hygiene and the use of Personal Protective Equipment (PPE) can help prevent contamination. Precautionary practices such as control sampling of a collector's hands before evidence collection can demonstrate the absence of GSR particles that could be a source of contamination.

In order to evaluate the potential for packaging to be a source of GSR contamination, the exterior of 100 GSR collection kit packages of varying types was sampled for GSR. Samples were blindly tested using Scanning Electron Microscopy/Energy Dispersive X-ray Spectroscopy (SEM/EDX) with automated software to detect particles characteristic of GSR by standard operating procedures.

Results showed that 12 of the 100 sampled packages yielded characteristic GSR particles. Of the twelve positive exteriors, three had more than one particle. The source of the GSR could not be determined but the packages were purchased by and in the control of the law enforcement agency prior to submission.

These results show that GSR evidence packaging should be treated as if it were contaminated. The laboratory should maintain separate package handling and analytical testing areas. Good practices should include wiping GSR packaging at evidence intake, regular cleaning of dedicated laboratory packaging area and analytical areas, and the use of PPG and good hygiene practices.

In conclusion, this presentation will illustrate a potential source of GSR laboratory contamination and will provide suggested actions that may be taken to mitigate its occurrence.

GSR, SEM, Contamination

B33 Fourier-Transform Infrared Spectroscopy Investigations of Smokeless Powders

*Quashanna Price**, National Center for Forensic Science, 12354 Research Parkway, Orlando, FL 32816-2367; *Mary R. Williams, MS*, PO Box 162367, Orlando, FL 32816-2367; and *Michael E. Sigman, PhD*, University of Central Florida, National Center for Forensic Science, PO Box 162367, Orlando, FL 32816

The goal of this presentation is to determine whether novel smokeless powder classes can be identified beyond the single-base and double-base designations by statistical analysis of Fourier-Transform Infrared Spectroscopy (FTIR) data.

This presentation will impact the forensic science community by providing a statistically valid classification method for powders exclusive of the classic division of single-base and double-base designations.

In 2009, the National Center for Forensic Science (NCFS) developed a smokeless powders database in conjunction with the Technical/Scientific Working Group for Fire and Explosives Analysis (T/SWGFEX) regarding the analysis of smokeless reloading powders. Smokeless powders are low explosives that contain energetic materials and function as propellants in reloading ammunition and they are frequently found in Improvised Explosive Devices (IEDs) such as pipe bombs. The three main types of smokeless powders are single base, double base, and triple base, with all three types containing nitrocellulose. In addition to nitrocellulose, double-base powders contain nitroglycerin while triple-base powders contain nitroglycerin and nitroguanidine. The smokeless powders database housed by NCFS contains analytical data for a large number of commercially available single-base and double-base powders that have been analyzed through analytical methods including Gas Chromatography/Mass Spectrometry (GC/MS), stereomicroscopy, and FTIR.

For this research, FTIR data for 87 smokeless powder samples analyzed at NCFS were utilized. The percent transmittance (%T) was converted to absorbance and the intensity values for wavenumbers 400-4,000 cm^{-1} were normalized to scale 0-1. Since no prior information was known regarding potential grouping of the data, an unsupervised technique, Agglomerative Hierarchical Clustering (AHC) was used to generate dendrograms showing the clustering groups of powders based on FTIR. Hierarchical clustering utilizes a distance metric (i.e., Euclidean, maximum, etc.) to calculate the distance between samples and a linkage-metric (i.e., single, complete, etc.) to cluster data.

Further studies included defining the appropriate distance and linkage by creating dendrograms using Euclidean distance and single, complete, and ward linkage-methods to determine the best clustering. It was determined that the distance and linkage combination of Euclidean and Ward, respectively, gave partially overlapping clusters. The similarity data was then used to generate a heat map to visualize the groupings.

Preliminary results from cluster analysis identified four groups among single-base and double-base powders that do not cluster based on the presence or absence of nitroglycerin, indicating that there are additional factors influencing cluster formation. Additional research will seek to determine the chemical factors contributing to the clustering. In addition, 2D mapping studies of smokeless powder cross-sections will be performed to investigate heterogeneity throughout the kernel.

This work was supported in part by the National Institute of Justice, Office of Justice Programs, award 2013-R2-CX-K008. The content of this publication does not necessarily reflect the position or the policy of the government, and no official endorsement should be inferred. Cluster Analysis, Smokeless Powders, Statistics

B34 Creating a Bayesian Network Using Normalized IBIS Scores of .357 Magnum® and .38 Special Cartridge Cases

*Roger Jefferys**, 27 Dafonzo Hill Road, Pursglove, WV 26546; *Emily B. Fabyanic**, 2262 Fleegle Road, Central City, PA 15926; *Eric Law**, 1612 District Drive, Morgantown, WV 63701; and *Keith B. Morris, PhD**, 208 Oglebay Hall, 1600 University Avenue, PO Box 6121, Morgantown, WV 26506-6121

After attending this presentation, attendees will understand that transformations through normalization of the correlation scores of the firing pin and breech face influence the likelihood ratio. The Receiver Operator Curves (ROCs) of the firing pin and breech face ranks, including the product of the two, are different from the normalized ROCs of the firing pin, breech face, and their product. A firearms examiner can make a more informed decision by using normalized Integrated Ballistic Identification System® (IBIS®) scores.

This presentation will impact the forensic science community by demonstrating that transforming the IBIS® correlation scores through normalization affects the accuracy of the results. The generation of ROCs from both non-normalized and normalized data sets will show the influence that the variation in data has on the likelihood ratios.

The IBIS® developed by Forensic Technology International, serves as the backbone of the National Integrated Ballistic Information Network (NIBIN) system.¹ This system allows for the databasing of images of cartridge cases and bullets. For each cartridge case, two areas are imaged: the firing pin impression and the breech face impression. All of the cartridge cases were entered into the 2D IBIS® system in order to generate the match data. The acquisition method followed was established in a previous study.² The data was mined to evaluate the variance between relationships involving the following variables: firing pin rank, breech face rank, make and model of the firearm, the ammunition used, caliber, and type of primer reload (if any).

The research involved the acquisition of .357 Magnum® and .38 Special revolver cartridge cases from 15 .357 Magnum® firearms and eight .38 Special firearms. The .357 Magnum® revolvers were used to fire both .38 Special and .357 Magnum® cartridges. The IBIS® compares unknown .38 Special cartridge cases to known (in the database) .38 Special and .357 Magnum® cartridge cases, but only compares unknown .357 Magnum® cases to known .357 Magnum® cases.

A ROC can be used to determine the crossovers between match and non-match. ROCs demonstrate the discriminating power of the method. Normalized and non-normalized ROCs were generated for each individual .38 Special and .357 Magnum® firearm used.

Normalization originates from statistics and eliminates the unit of measurement by transforming the data into new scores (Z-scores) with a mean of zero and a standard deviation of one.³ Normalizing a set of scores involves subtracting the sample mean from the score and then dividing by the standard deviation of the sample. For the purpose of this research, the mean and standard deviation of a variety of sampling percentages of non-match scores for each firearm was found and then used to convert each cartridge case fired from that firearm to a Z-score. This was performed for firing pin, breech face, and their product.

A Bayesian network was used to determine the relationship between the IBIS® scores from the cartridge casings that were collected from the firearms in this study. Scores from IBIS®, such as Firing Pin (FP), Breech Face (BF), and rank (BF/FP) scores were included, as well as factors controlled by the analysts, such as the make/model of the firearms of a chosen caliber. Four new concepts were added as part of the network. They included: breech face rank, normalized firing pin and breech face scores, and the normalized multiplication of the two. The network includes a node titled “Match” and depending on what is instantiated in the network, the probability of a match fluctuates (this will be demonstrated using a computer while presenting). These match and non-match probabilities can then be used to calculate a likelihood ratio based on assigned prior odds. The match/non-match probabilities act in support of $P(H_p|E)$ (probability of the prosecutorial hypothesis being true, given the evidence) or $P(H_d|E)$ (probability of the defense hypothesis being true, given the evidence), respectively.⁴

Transformation of the scores through normalization can lead to improved accuracy of results.

Firearms, Bayesian Networks, Normalization

B35 Weathering and Microbial Degradation of Ignitable Liquids

Jessica H. Kindell, BS*, National Center for Forensic Science, 12354 Research Parkway, Ste 225, Orlando, FL 32826; Mary R. Williams, MS, PO Box 162367, Orlando, FL 32816-2367; and Michael E. Sigman, PhD, University of Central Florida, National Center for Forensic Science, PO Box 162367, Orlando, FL 32816

The goal of this presentation is to help attendees understand the purpose of the updated Ignitable Liquid Reference Collection database, pattern recognition of a reference ignitable liquid when weathered and/or degraded, and see an example that ties together weathering and microbial degradation of a simple mixture.

This presentation will impact the forensic science community by presenting the updated database in regard to weathering and degradation and by demonstrating these mechanisms quantitatively on a simple mixture.

Fire debris evidence is important in arson investigations in regard to finding the origin and cause of a fire. Most ignitable liquids are complex mixtures composed of many organic compounds that are exposed to weathering and/or microbial degradation. With both of these mechanisms either simultaneously or individually affecting the ignitable liquid, it may be difficult for an analyst to assign class and subclass based on the criteria established by the American Society for Testing and Materials (ASTM) E1618. In this research, a simple mixture was made from 14 known compounds which are commonly found in different ASTM classes and was made to undergo both weathering and microbial degradation. Each compound was degraded separately to see if any by-products that formed would coincide with compounds that may normally be present in a complex ignitable liquid. Additionally, a quantitative assessment was performed to observe and record the relative rates of degradation of the compounds found in the simple mixture. The purpose of this research was to measure the effects on a simple liquid mixture as a result of introducing soil containing bacteria. This research further quantifies the rate of compound degradation compared to the use of complex liquids which utilize pattern recognition that only indicates the presence or absence of a given compound or compound type.

Databases are designed and available, both in in-house laboratories and nationally, to aid investigators in connecting fire debris evidence to a potential source by comparing the total ion chromatograms and extracted ion profiles. The Ignitable Liquid Reference Collection (ILRC) has been extended to include examples of weathered and biologically degraded liquids from each ASTM class. The results of the weathering and biological degradation database will help investigators understand what components of the ignitable liquids are being recovered and which components are lost.

Passive-headspace adsorption/elution and gas chromatography/mass spectrometry methods were used in accordance with ASTM E1618. For weathering, 10 milliliters of an ignitable liquid were evaporated to the percentages 25%, 50%, 75%, 90%, and 95% using nitrogen gas. Twenty microliters of the weathered liquid were placed into a vial with one milliliter of carbon disulfide and analyzed. For the purpose of degradation, potting soil was spiked with an ignitable liquid in a quart-sized paint can, which was then sealed for a specified period of time (zero, two, seven, or 14 days). An activated charcoal strip was then placed in the can's headspace and heated in an oven at approximately 85°C for approximately four hours. Once removed and cooled to room temperature, the strip was eluted using 500 microliters of carbon disulfide and analyzed.

The results of the weathered ignitable liquids were compared to the neat chromatograms in regard to what compounds were still present and if the ASTM classification was the same. Microbial degradation results revealed what compounds the bacteria prefer and comparison of the relative rates at which different compounds degrade. The results have been compiled into the ILRC to assist the analyst in visualizing the pattern of weathered and degraded samples based on evaporation percentages and time period of soil exposure. Results from the microbial degradation of a simple mixture reveal that no by-products were formed when the 14 components were tested separately for zero, seven, and 14 days. Experimental investigation of the quantitative losses of the components of a simple, but representative mixture of hydrocarbons through biological degradation is ongoing. This presentation will provide data representing the enhanced utility of the ILRC and quantitative results from the biological degradation of a simple mixture of hydrocarbons.

Ignitable Liquids, Weathering, Microbial Degradation

B36 Analysis of Anthraquinone Dyes by Electrospray Ionization Quadrupole-Time-of-Flight Tandem Mass Spectrometry (ESI-QTOF-MS/MS)

Nelson R. Vinueza, PhD, North Carolina State University, 2401 Research Drive, Campus Box 8301, Raleigh, NC 27695*

After attending this presentation, attendees will understand how tandem mass spectrometry on a Quadrupole Time-of-Flight (QTOF) can provide structural elucidation of acid dyes extracted from fibers by specific key fragmentation patterns and how these data can be used to unambiguously identify commercial textile dyes.

This presentation will impact the forensic science community by providing an improved and faster analysis of dyed fiber by imparting a better understanding of the dye fragmentation pathways on a QTOF mass spectrometer for better identification compared to current methods.

In forensic analysis, textile fibers are frequently encountered as evidences in forensic crime scenes. Unambiguous identification and characterization of the dyes present in the fibers are of significance for forensic analysis. Several analytical methods such as Fourier Transform Infrared (FTIR), Ultraviolet/Visible (UV-Vis) spectroscopy, and Nuclear Magnetic Resonance (NMR) can be used for the identification of dyes; nevertheless, the low quantities of trace evidence found at crime scenes can hinder their analysis by these methodologies. Mass spectrometry offers an excellent option for analysis of trace evidence of dyes, due to its high sensitivity and versatility. In this sense, ESI-QTOF-MS/MS can be used for efficient identification and characterization of dyes.

This study is the first stage on the building of a mass spectrometry dye database from the recently donated Max Weaver dye library from Eastman® Chemicals, with approximately 100,000 dyes, to the College of Textiles in North Carolina State University. In this study, several sulfonated anthraquinone acid dyes containing the structure of 1-amino anthraquinone-2-sulfonate acid were analyzed by ESI-QTOF-MS/MS. A loss of 64amu was observed for all dyes and model compounds. This loss was confirmed to be SO₂ by high-resolution analysis. The unimolecular rearrangement and mechanisms of fragmentation triggered by Collision-Induced Disassociation (CID) were investigated by tracing the sulfur isotopes, ³²S and ³⁴S, as well as by exploring the functions of the ortho-amino group during the rearrangement. Also, it was found that the presence of different group functionalities (e.g., secondary or tertiary amines and thiols) attached to the anthraquinone structure have specific fragmentation pathways under similar CID conditions that can be used to identify them. For example, an anthraquinone having a secondary amine with an aromatic group attached to it (e.g., acid blue 25), can be distinguished from an anthraquinone having a secondary amine with an alkyl group attached to it (e.g., acid blue 62). The resultant fragmentation patterns could contribute to a dye database for identifying and fingerprinting unknown dyes with similar chemical structures and can be used for trace fiber evidence in forensic analysis.

Mass Spectrometry, Dyed Fibers, Trace Evidence

B37 Expert Witness Testimony and DNA Evidence in South Africa

Antonel Olckers, PhD, DNAbiotec (Pty) Ltd, 25A De Havilland Crescent, Persequor Park, Pretoria, Gauteng 0020, SOUTH AFRICA*

After attending this presentation, attendees will understand that the diligence and manner in which DNA evidence is processed and interpreted in the South African justice system should indeed serve justice. The contributing factors that prevent this from happening, as well as relevant solutions, will be discussed.

This presentation will impact the forensic science community by explaining how contesting DNA evidence in South African courts is not the norm. In addition, there are few independent DNA experts to assist either the prosecution or the defense and bias is rife. The forensic science profession is not regulated and the national laboratory of the state is not accredited. All of the above factors have contributed to a less-than-ideal situation in terms of the criminal justice system in South Africa and, indeed, justice itself.

Even though the status quo does not always serve justice, it does maintain a high conviction rate — which is sometimes the only metric employed to measure “success” in terms of forensic science in South Africa.

Over the past 16 years, South Africa has observed that bias testimony is prevalent and mostly accepted by the courts. Since the first case where DNA evidence was contested in depth, *State v. Maqhina*, there have been some improvements in how DNA evidence is presented in court. There have also been improvements in the discovery process, albeit that both these improvements came about after judgments that were not in favor of the State in significant/key cases.

The level of science is not high when testimony is delivered in court. Statements of identity are common and the bias is perpetuated throughout the system in case after case. Specific examples will be discussed to illustrate what the level of science is in the current status quo. Is there a solution to this for the South African justice system?

Although the solution seems logical, its implementation will require a totally new frame of mind at various levels, including science, law, and policy, in order to truly serve justice. At a minimum, the following will be required in order to address the above challenges: (1) regulation of the forensic science profession in South Africa; (2) accreditation of forensic science laboratories; (3) correct interpretation of DNA evidence — a major factor; (4) addressing the lack of scientific knowledge by forensic scientists; (5) interaction with other forensic science professionals and peers at the national and international levels; (6) transparency with regard to processes followed in the forensic community; (7) eliminating the emphasis on the prosecuting perspective; and, (8) trained legal professionals that can competently handle DNA evidence in court.

Regulation of the profession is key since it will put measures in place to allow the ethical practice of science. Without this aspect, the bias that currently prevails in the system will not be eradicated and justice cannot be served. It will also serve to lift the level of science in the courts, as testimony should be scientifically correct and not mere assumption.

No perfect system exists in forensic science globally; however, if the above can be addressed in South Africa, regardless of how steep the climb to achieve it is, at least justice will be served — as promised to the people of South Africa in the Constitution.

To achieve this goal, both the scientific and legal professionals in South Africa will have to work together in order to bring about the change, without which justice in the forensic science context will remain elusive in South Africa.

DNA Evidence, Interpretation, Ethics

B38 Forensic DNA Collection at Death Scenes

Balvina Zurinne Phillips, MS, 1885 Old Spanish Trail, Houston, TX 77054; Christy Smejkal, MS, Harris County MEO, Forensic Genetics Section, 1885 Old Spanish Trail, Houston, TX 77054; Rhonda C. Williams, PhD, 800 E 2nd Street, Oklahoma State Bureau of Investigation, Edmond, OK 73034; and Roger Kahn, PhD, Harris County Institute of Forensic Science, 1885 Old Spanish Trail, Houston, TX 77054*

After attending this presentation, attendees will have a better understanding of the operations of a team of forensic DNA analysts called to select death scenes to collect trace DNA evidence. Case examples will be presented to outline successes from recovering foreign DNA from decedents.

This presentation will impact the forensic science community by informing attendees of the importance of collecting and preserving trace evidence from decedents at death scenes and the impact such evidence has in providing valuable investigative information.

The Trace DNA Evidence Collection Team at the Harris County Institute of Forensic Sciences (HCIFS) is a group of qualified DNA analysts that respond to death scenes for the purpose of collecting trace and DNA evidence from decedents' bodies prior to transport to the morgue. Team members from the Forensic Genetics laboratory provide on-call coverage 24/7. They respond to homicides where close contact is suspected to have occurred between the perpetrator and victim. Evidence such as hairs, fibers, body fluids, and potential areas of touch DNA are collected from the body at the scene to prevent possible loss during transport to the morgue.

A guide is provided to HCIFS medicolegal death investigators to aid them in determining whether to dispatch a Trace DNA Evidence Collection Team member to collect evidence at a scene. Evidence of close contact between the decedent and a perpetrator, such as signs of a struggle, blunt force trauma, or possible evidence of sexual assault, as well as cases where the body has been transferred or dumped, will lead to a call-out. The Trace Team would not be called to collect from highly decomposed or skeletonized bodies or bodies submerged in water. If the scenario suggests evidence may be present but it is not likely to be lost during transport of the body, the decedent may be sealed in a body bag for trace evidence collection at the morgue just prior to autopsy. This might be the case, for example, for a body that is dry or has minimal blood on it.

A surprising number of positive DNA results from victims of gunshot wounds have been noted. DNA foreign to the victim has been found in at least 20 gunshot wound cases from the decedent's pockets that were turned inside out and on facial bruises. The turned-out pockets and bruises indicate close contact, so these cases meet the call-out policy despite use of a firearm.

Between 2009 and 2013, the team responded to 345 scenes. Forty-six of the cases yielded DNA foreign to the decedent. Of the 46 cases, 31% yielded one to ten foreign DNA alleles, while 69% yielded more than ten alleles. In 18 of the cases (35%), the DNA was found to be consistent with a known suspect named in the case. In addition, two DNA profiles obtained from evidence collected by the Trace Team resulted in Combined DNA Index System (CODIS) hits. Both CODIS hits involved unclothed female decedents found outside. In the first case, a pair of hand cuffs used to bind the decedent were swabbed and the resulting profile hit on a suspect in CODIS. For the second case, a stain on the decedent's calf was swabbed and the resulting profile developed a suspect in CODIS, which ultimately led to a confession by the individual.

The Trace DNA Evidence Collection Team is one of the only organized teams associated with a medical examiner's office that regularly collects evidence from decedents at death scenes. This team has become an integral part of the HCIFS medical examiner service. The HCIFS hopes the unexpectedly high success rate of recovering foreign DNA from decedents will encourage others to establish this type of program.

Touch DNA, Death Scenes, Evidence Collection

B39 The Making of the Criminalistics Maestro — On the Skills, Knowledge, and Abilities to Work Proficiently on Non-Routine and Complex Cases

Peter R. De Forest, DCrim, PO Box 141, Ardsley, NY 10502; Patrick Buzzini, PhD, West Virginia University, 1600 University Avenue, 304, Oglebay Hall, PO Box 6121, Morgantown, WV 26506-6121; Rebecca E. Bucht, PhD, Pietarinkatu 11 A 13, Helsinki 00140, FINLAND; Carol L. Hunter, BS; and Douglas M. Lucas, DSc, 5280 Lakeshore Road, #1111, Burlington, ON L7L 5R1, CANADA*

After attending this presentation, attendees will better understand which skills, knowledge, and abilities a criminalist should acquire to work proficiently on non-routine and complex cases as opposed to routine-based laboratory tasks.

This presentation will impact the forensic science community by stimulating discussions about the education and training of forensic science practitioners and on how one becomes an effective generalist in defining the problems to be investigated and in coordinating criminalistic investigations.

In this age of increasing scientific specialization, some have argued that time and scientific advances have passed the generalist scientist by. They argue that one cannot be a generalist or that the generalist is an outdated concept with no value in this day and age. Conversely, others have argued for the need for generalists as well as specialists. The debate has been especially apparent in criminalistics. A committed proponent of one side or the other typically has little understanding of the other's position. Each may be attracted to absurdist descriptions of the other's position. The generalist may be described as someone who knows less and less about more and more until ultimately he/she knows virtually nothing about everything. On the other hand, the specialist is characterized as learning more and more about an increasingly narrow area until he/she knows everything about nothing. Clearly, the truth lies between these two extremes. A useful analogy is that of the symphony conductor or maestro and the musicians who make up the orchestra. The maestro may be unable to master a particular musical instrument to the world-class level expected of a musician in the orchestra but is a master of understanding how the contributions of all of the instruments and musicians contribute to the success of the orchestra. Of course, there is nothing to prevent a conductor from being a virtuoso on one or a limited number of instruments but such an individual cannot be a master of all. The maestro would not be expected to be. The strength and purpose of the maestro lies elsewhere.

Previous discussions advanced the concept that criminalists should be involved at the outset of the investigation of non-routine and complex cases. Further, the criminalists will be the ones to define and circumscribe the scope of the scientific investigation of the physical evidence record. Unfortunately, in most jurisdictions, criminalists are limited to examining some preselected portion of this record. They are constrained by established customs and practices. They are prevented from seeing the "big picture" and having a major role in defining the physical evidence problem to be investigated. To some extent, this issue is starting to be addressed through efforts to provide quality assurance in the form of International Organization for Standardization (ISO) accreditation of crime scene work as well as the (re)discovery of possible generalist criminalist functions such as forensic case managers or case assessors/evaluators; however, care needs to be taken to ensure that the people chosen, educated, and trained for this key role possess the necessary skills, knowledge, and abilities to tackle their responsibilities, especially in non-routine and complex cases. It is imperative that these individuals are scientists/criminalists rather than technicians.

It is not banal to reiterate that every case and crime scene is different. Each presents challenging scientific problems. What scientific and non-scientific skills would, or should, a criminalist bring to this task? How can these skills, knowledge, and abilities be developed? Can they be taught?

This presentation is not going to take up the generalist/specialist debate. It is going to attempt to deal with the question of how one becomes an effective generalist in defining the problems to be investigated and in coordinating investigations involving physical evidence. How can this be done? This presentation will pose as many questions as solutions offered.

Generalist Development, Complex Cases, Case Management Skills

B40 The Failure of Forensic Science Academia to Address Perceived Scientific Shortcomings

Victor W. Weedn, MD, JD, George Washington University, 2100 Foxhall Road, NW, Somers Hall, Lower Level, L-12, Washington, DC 20007*

After attending this presentation, attendees will be aware of limitations in traditional forensic science education programs to generate adequate foundational scientific underpinnings for forensic science analysis of impression/pattern evidence.

This presentation will impact the forensic science community by bringing to light the limitations of traditional forensic science educational programs to address criticism lodged against the forensic science community in the area of patterned evidence.

Forensic science educational programs have mushroomed since *CSI* aired on television. In fact, a surplus of students has resulted. The quality of the educational programs has increased. Forensic science educational programs are moving to faculties with more than a single member; in fact, all Forensic Science Education Programs Accreditation Commission (FEPAC) -accredited programs have multiple full-time forensic science faculty members. FEPAC has been launched. Nonetheless, despite significant progress, some problems in forensic science education, discussed in the 2004 Technical Working Group on Education (TWGED) report, have in some ways deepened. There is still too little hands-on laboratory analysis in many programs. But what has received less attention is a faculty knowledge gap. Over and over, forensic science programs are bringing chemists and molecular biologists into their faculties, but other forensic science disciplines are generally getting short shrift. There are virtually no questioned document examiners, firearms and tool marks examiners, latent print examiners, or bloodstain pattern analysts as full-time faculty members. University accreditation commissions require a terminal degree for faculty positions — in particular, a PhD degree is sought. Of course, there are no PhD programs in questioned documents examination, firearms and tool marks examination, tire marks examination, etc. Thus, there is a chicken-and-egg situation that results in the continuation of this gap in forensic science academia. Universities do not seem to know how to address this gap. The result is that research in the underlying foundational science that has been called for in the patterned and impression evidence area is lacking.

The 2009 National Academy of Sciences (NAS) Report, *Strengthening Forensic Science in the United States: A Path Forward*, declares, "...the major forensic science disciplines...those that are used most commonly for investigations and trials...have been cause for concern in court or elsewhere because their reliability has not been sufficiently established in a systematic (scientific) manner..." *Chemical and Engineering News* recently reported, "Five years ago, the National Academy of Sciences put out a report condemning the state of forensic science. It concluded that many common forensic techniques — the analysis of fingerprints, bite marks [sic], blood splatter [sic], and ballistics, for example — lack sufficient scientific underpinnings. Thousands of convictions were thrown into question. But in the years since, little has been done to shore up the discipline's scientific base..." There is, of course, some research in these areas, but not as much as there should be. Some of this research is performed in collaboration with true expert practitioners, but some research is being conducted by academicians without deep understandings. Furthermore, the absence of doctoral students hampers research in the field. The presentation will end by discussing a concept to fill in this expertise and research gap by creating an innovative new PhD program, in which the professors are non-experts and the students are experts.

Forensic Science Education, Research Gaps, Patterned Evidence

B41 Implementing Independent Research Projects in a Graduate Forensic Science Degree Program

Walter F. Rowe, PhD, George Washington University, Dept of Forensic Science, 2100 Foxhall Road, NW, Washington, DC 20007*

After attending this presentation, attendees will understand the problems involved in implementing a program of independent research projects as required by the Forensic Science Education Programs Accreditation Commission (FEPAC). These problems include obtaining adequate resources (such as instrumentation, reagents, and samples) and recruiting external members of research committees.

This presentation will impact the forensic science community by showing the value to the forensic science field of independent research projects conducted by graduate students in forensic science degree programs and by encouraging forensic science practitioners to participate in such research projects as principal investigators or as members of research committees.

One of the accreditation requirements of FEPAC for forensic science graduate degree programs is that each student successfully complete an independent research project. Successful completion entails writing a publishable manuscript reporting the student's research results and a public presentation of the results before the student's research committee. The research committee has to have a minimum of three members, one of whom must be from outside the forensic degree program. Studies validating existing analytical methods for use in a particular laboratory are excluded as acceptable research projects.

While few forensic science laboratories conduct research (the overwhelming majority being casework laboratories), future forensic analysts benefit from conducting successful research projects. First of all, research projects provide opportunities for students to gain greater experience in the operation of analytical instruments and in the interpretation of results. Research projects also hone problem-solving skills. Finally, the required manuscript and oral presentation before a committee of experienced scientists gives the students further experience with communicating scientific ideas, experience which is directly applicable to report writing and courtroom testimony.

At The George Washington University, the Department of Forensic Sciences has had to deal with a number of issues in establishing a viable master's-level research program as a part of its Master of Forensic Science (MFS) degree program. First, it was realized that students need to start on a research project early in their degree programs. This allows time for the student to recover from delays resulting from such events as instrument breakdowns or failure of a series of experiments. One particularly vexing delay has proven to be obtaining Institutional Review Board (IRB) approval for projects involving human research (which means most forensic molecular biology projects). Students conducting research in federal government laboratories have also been shut out of these laboratories during government shutdowns.

To insure that projects move along in a timely manner, the department has developed a form on which the MFS student outlines the proposed research project, detailing the experiments to be performed, proposed data analysis, a timeline for conducting the experiments and reporting the results to the student's research committee, and a list of assets required to complete the project (such as instruments, reagents, and samples). This proposal is submitted to the student's research committee for revision and final approval. The department has been able to recruit research committee members from other departments within the University and also from state and federal laboratories in the Washington, DC, area.

Because each year the department has a large number of MFS students who require research projects, it has been difficult to find enough viable projects and sufficient resources for conducting them. Some students have been able to conduct their research in one of the federal government laboratories in the Washington, DC, area. Senior scientists in these laboratories have been willing to serve as principal investigators/mentors for the students. Their laboratories benefit, of course, by having students carry out research that the laboratories otherwise lacked the manpower to accomplish. Departmental resources have also had to be devoted to support student research projects. Departmental faculty members are actively seeking external funding for research; however, under the best of circumstances only a fraction of the MFS students will have external support for their research. The large number of MFS students conducting research has also required full-time faculty of the department to serve on multiple research committees.

As discussed above, FEPAC requirements that graduate forensic science students conduct independent research projects enhance the educations of the students, but present the directors of the graduate degree programs with a number of ongoing challenges involving availability of resources and personnel.

FEPAC, Forensic Science Research, Forensic Science Education

B42 Strengthening Forensic Science in the United States: An Update on National Efforts in Research and Development

Gerald M. LaPorte, MSFS, National Institute of Justice, Office of Inv & Forensic Science, 810 Seventh Street, NW, Washington, DC 20531*

After attending this presentation, attendees will have a greater understanding of how the forensic science community has progressed in the area of research and development. Attendees will also be aware of findings from studies that are having an impact on the forensic science community and potential areas that require additional research.

This presentation will impact the forensic science community by providing an update on national efforts to bolster the quantity and quality of forensic science research studies since the 2009 National Academy of Sciences (NAS) Report, *Strengthening Forensic Science in the United States: A Path Forward*. This presentation will provide an overview of some studies that are beginning to have a positive impact on the perception that forensic science has been lacking in research.

Since 2009, the National Institute of Justice (NIJ) has provided more than \$120 million to fund more than 300 research and development projects related to forensic science, resulting in more than 600 scientific publications, presentations, and final technical reports. In March of 2009, NIJ immediately began addressing recommendations in the NAS Report. There were two major recommendations made in the 2009 NAS Report related to scientific research. Recommendation three called for more research to address issues of accuracy, reliability, and validity in the forensic science disciplines. Recommendation six was to encourage research programs on human observer bias and sources of human error in forensic examinations. More specifically, there was an emphasis on the impression and pattern evidence disciplines such as friction ridge analysis, firearms and tool mark examinations, shoeprint and tire tread evidence, questioned documents, and bloodstain pattern analysis. Therefore, this presentation will focus specifically on progress in the impression and pattern evidence disciplines. NIJ's efforts have earned the support of many respected leaders in the scientific community, including members of the American Academy of Forensic Sciences (AAFS). Douglas H. Ubelaker, former President of the AAFS, wrote in an article to the membership, "A recent major boon to research in forensic science has been the National Institute of Justice's Office of Investigative and Forensic Sciences (OIFS) whose sole goal is to strengthen the quality and practice of forensic science." Most importantly, the presentation will clearly demonstrate that research and innovation are the core requirements needed to continue the progress that has been attained and to strengthen the science in forensic science.

Research and Development, NAS Report, Strengthening Forensic Science

B43 Mentorship to Colleague Inspired by Service: An Evolution to a Brother- and Sister-in-Law Forensic Family Relationship

Desiree A. Reid, BS, NJ State Police, East Lab, Sea Girt Avenue, Sea Girt, NJ 08750; and Lawrence Quarino, PhD*, Cedar Crest College, Dept of Chemistry & Physical Science, 100 College Drive, Allentown, PA 18104*

After attending this presentation, attendees will be shown how a mentoring relationship can evolve to a peer relationship and sometimes may also lead to a family connection.

This presentation will impact the forensic science community by showing how a “forensic science family” relationship was shaped by two individuals who rose to leadership positions in forensic science.

Larry Quarino and Desiree Reid met in 1984 at John Jay College of Criminal Justice in New York City. Desiree was an undergraduate working toward her Bachelor of Science degree in Criminalistics while Larry began work toward a Master of Science in Forensic Science. Both studied under Dr. Peter De Forest who always emphasized the importance of service to the forensic science community. John Jay students regularly attended professional conferences and Larry and Desiree understood what was expected of them as future criminalists and professionals.

Larry and Desiree always had a close friendship and Larry’s fiancée, Denise, always tried to find a nice boyfriend for Desiree. Larry also kept his eyes and ears open to help Desiree get the proverbial foot in the forensic door. That door was opened one day when Desiree was afforded the opportunity to pursue a summer internship at the New Jersey State Police North Regional Lab, where Larry worked in what was referred to in those days as the Serology Unit. Larry was assigned stewardship of the new intern and became her mentor. Larry had such confidence in Desiree’s abilities to perform tasks that he occasionally got in trouble for giving Desiree an excessive amount of responsibility. Larry believed so strongly in Desiree’s future potential as a criminalist that he convinced a coworker to persuade his wife to hire Desiree in her laboratory. After sojourning a few years at the Union County, NJ, Prosecutor’s Office Forensic Science Laboratory, Desiree was offered a drug chemist position at the North Regional Lab in 1989; however, Larry’s and Desiree’s reunion was short-lived, since within a few months of Desiree’s start date, Larry left for a supervisory position with the brand new Department of Forensic Biology at the Office of Chief Medical Examiner in New York City.

Although Larry and Desiree no longer worked together, they maintained a friendship. Larry and Desiree were among the inaugural group who took the American Board of Criminalistics (ABC) General Knowledge Examination at the 1993 American Academy of Forensic Sciences (AAFS) meeting in Boston and, happily, both passed. Both Larry and Desiree are huge supporters of certification and both have served on the Board of Directors of the ABC. Desiree even had the honor of serving as president of the organization for several years.

Desiree’s commitment was never more evident than in the weeks and months after the attacks of September 11, 2001. For several months, Desiree (as well as many others) gave up weekends to work as an unpaid volunteer at the New York City Office of Chief Medical Examiner on the World Trade Center Identification project. Larry, on the other hand, earned a doctorate in 2000 and embarked on a career as a forensic science academician. He has served as a Commissioner and Chair of the Forensic Science Education Program Accreditation Commission and currently serves as the Chair of the Criminalistics Section of the AAFS and is President-Elect of the Northeastern Association of Forensic Scientists.

Denise, now Larry’s wife, finally did find a special someone for Desiree: her brother Anthony. Desiree and Anthony were married in 2006. Even though Larry’s and Desiree’s professional relationship has changed from one of mentorship to colleagues and their personal relationship has changed from friends to brother- and sister-in-law, they continue to be supportive of each other’s careers. A few years ago, Desiree gave a talk on drug chemistry to the students at Cedar Crest College where Larry serves as program director and recently Desiree reached out to Larry for help with a drug chemistry project. Nobody from their John Jay days could have ever imagined how Desiree and Larry would one day find themselves in a “forensic family.”

Forensic Family, Reid, Quarino

Criminalistics Section - 2015

B44 Scientific and Technical Support of Dangerous Mail Investigations

Stephanie L. Smith, BS, United States Postal Inspection Service, TSU/NLECC, 22340 Dresden Street, Ste 195, Dulles, VA 20166-9315; and David G. Bowers, BS, United States Postal Inspection Service, Security & Crime Prevention Group, 475 L'Enfant Plaza, SW, Washington, DC 20260*

After attending this presentation, attendees will understand some of the ways that scientific and technical support has been extended to the law enforcement professionals comprising the United States Postal Inspection Service's Dangerous Mail Investigations (DMI) Program. This program has fundamentals in science, but is staffed and administered by law enforcement personnel, typically without such backgrounds. This model of scientific support may be beneficial for other agencies.

This presentation will impact the forensic science community and various law enforcement and/or "first responder" communities by demonstrating the value of applying the knowledge, skills, and abilities of an experienced forensic chemist, including in ways that are non-traditional.

The law enforcement and "first-responder" communities are often unaware of the myriad ways that scientists can support their mission beyond the obvious examination of evidentiary materials. Similarly, forensic scientists are often precluded from extending their services beyond more traditional roles. It is the position of this presentation that there is great value in reliance upon scientific personnel when matters of scientific importance are encountered.

This study will introduce attendees to the United States Postal Inspection Service's DMI Program, including the events precipitating the creation of the specialized program along with its unique mission. The presentation will include the policies and procedures of the program from the fitness and training requirements for qualified specialists, to threat assessment practices, deployment, and competent/safe use of specialized equipment and instruments. Typical casework will be used to exemplify the manner in which these policies are implemented.

Attendees will learn about the duties and responsibilities established for the Scientific and Technical Advisor (STA) to the DMI Program, the underlying knowledge skills and abilities expected to execute the requirements of the position, and the strong correlation to those qualifications that might be expected of an experienced forensic chemist. The STA is expected to: (1) provide specialized expertise and leadership to evaluate and recommend practices that will optimize the assessment of threats to the United States mail; (2) conduct innovative and complex research; (3) serve as an authoritative source and subject matter expert by liaising between program leadership and the larger scientific and law enforcement communities; (4) plan, coordinate, and conduct training; and, (5) manage a robust quality assurance and safety program. To perform these duties, the STA is expected to possess: (1) the knowledge of forensic science theories, techniques, protocols, and methodologies; (2) the ability to identify and solve complex problems and develop sound recommendations; (3) the ability to communicate orally and in writing, especially with respect to presenting scientific information to a non-scientific audience; (4) the ability to develop and implement a program founded on best practices; (5) the knowledge of proper evidence practices, including the ability to support major field investigations; and, (6) the ability to represent the organization to peer groups, professional organizations, government officials, and industry representatives.

This study will provide examples of scientific and technical work completed in support of the DMI program, demonstrating how the successes of this model may translate to local, state, and federal laboratories and organizations, as well as within private entities.

Collaboration between forensic scientists and law enforcement professionals is prudent when the latter will rely upon complex technical equipment and protocols to conduct their mission. Such collaboration can facilitate the creation or advancement of a stronger program possessing a foundation employing quality assurance concepts and optimized practices. It is recommended that the forensic science community become familiar with the many ways its members can support the law enforcement and/or first responder community. Likewise, it is recommended that those communities become familiar with the abilities of their colleagues in the forensic science community.

Dangerous Mail, Scientific & Technical Advisor, Forensic Chemist

B45 Use of Lean Six Sigma Methodology to Improve Laboratory Productivity and Reduce Backlog

*Stefany E. Harman, MS**, 124 Acton Street, Maynard, MA 01754; *Maureen McCabe, MS*, Massachusetts State Police Crime Laboratory, 124 Acton Street, Maynard, MA 01754; *Lynn A. Schneeweis, MS**, 124 Acton Street, Maynard, MA 01754; *Kristen Sullivan*, 124 Acton Street, Maynard, MA 01754; *Heather Jamieson, MS*, Sorenson Forensics, LLC, 2495 SW Temple, Salt Lake City, UT 84115; and *Craig Nolde, BS*, 2495 SW Temple, Salt Lake City, UT 84115-3057

After attending this presentation, attendees will better understand how a laboratory can increase productivity and reduce case backlogs by implementing a workflow optimization method called Lean Six Sigma (LSS).

This presentation will impact the forensic science community by improving the experience and potential for success for laboratories considering implementing LSS concepts within their laboratory.

In 2012, the Massachusetts State Police Forensic Services Group (MSPFSG) secured grant funding to address existing case backlogs in the forensic biology section. As part of this initiative, the MSPFSG completed a LSS project that evaluated the laboratory's workflow and implemented changes to increase productivity and efficiency. The project team included two facilitators from the consulting agency and 12 MSPFSG members representing the Evidence Control (ECU), Criminalistics, Case Management (CMU), and DNA sections. The ultimate goal was to create a highly productive, quality-driven environment capable of meeting the demand for forensic biology examinations and eliminating the current backlog.

Employing the systematic process Define, Measure, Analyze, Improve, Control (DMAIC), the team evaluated the laboratory's current state and developed baseline metrics to monitor the progress of the project. Using data collected from the Laboratory Information Management System, current case demand and output were calculated and a project charter was constructed outlining specific, measurable goals and a timeline to achieve them. The forensic biology section spent approximately six weeks on the measurement phase eliminating all work in progress, mapping current processes to identify sources of process waste, and summarizing the current work and information flow. This data was analyzed to determine what changes could most significantly improve the overall process. A focused problem statement was developed by each unit with ideas for improvements to address these identified areas.

In Criminalistics, the improvement phase addressed extensive wait times between process steps and a lengthy review process. Data indicated that approximately 80% of errors identified during case review were administrative in nature. Consequently, standardized worksheets for evidence examination were created in place of "free-form" note taking, and ECU intake procedures were updated to address sources of administrative errors prior to case submission. The case assignment process was restructured to create smaller, more frequent case assignments and a standardized workflow schedule was designed to maximize the capacity of work completed in a five-day cycle; however, successfully implementing this schedule proved to be a challenge due to analysts' frequent court testimony and crime scene response. The unit is continuing to evaluate and modify the work flow and, despite these challenges, as of July 2014, the analysts' turn-around time decreased by 74% and the case review time decreased by 21%.

CMU focused on the case activation process for DNA testing and the method for obtaining authorization to consume samples of limited quantity. Many cases remained on the backlog indefinitely because they required critical documentation from the requesting agencies. Several redundancies were also identified in the case assignment process. The improved procedures streamline the activation of cases for DNA analysis and place specific timelines on the requesting agencies to provide the documentation required for analysis to proceed. Using these improved procedures, as of July 2014, the CMU case backlog decreased by approximately 30%.

In the DNA unit, the improvement phase focused on designing a schedule that condensed the workflow from 12 weeks to two weeks. This new schedule introduced standardized work practices, implemented a team-based approach, and defined expected daily tasks. Though the DNA unit needs to make further adjustments to meet the new schedule, as of July 2014, the average case turn-around time decreased from 202 to 102 days and the average analyst turn-around time decreased from 122 to 35 days. The control phase provided the unit with tools to monitor progress and a means for supervisors and management to predict the working capacity of the unit and the status of individual cases. This phase also introduced a significant shift in supervisory approach, with supervisors accountable for distributing work based on the DNA unit's daily needs and priorities.

Criminalistics Section - 2015

This study will present the journey of a large state laboratory implementation of LSS concepts. Though implementing these principles is not without operational challenges for a laboratory to consider, LSS provides effective tools for a laboratory striving to improve productivity and reduce backlog.

Productivity, Backlog, Quality

B46 Demystifying the American Board of Criminalistics Examination

David C. Stockwell, BS, Contra Costa Sheriff Forensic Services, 2530 Arnold Drive, Ste 200, Martinez, CA 94553; and Marie Samples, MS, OCME, Dept of Forensic Biology, 421 E 26th Street, New York, NY 10016*

After attending this presentation, attendees will understand how factors such as hours of study, educational background, and years of professional experience impact performance on the American Board of Criminalistics (ABC) certification examinations.

This presentation will impact the forensic science community by offering information that will help individuals understand the purpose of the ABC, the history of the examinations, their success rate, and their performance trends.

In light of the 2009 National Academy of Sciences Report, *Strengthening Forensic Science in the United States: A Path Forward*, and the subsequent creation of the National Commission on Forensic Science, many forensic scientists are considering pursuing certification. The ABC at present provides a path to professional certification to forensic scientists seeking peer recognition of competency in six areas of criminalistics (Comprehensive Criminalistics, Drug Analysis, Fire Debris, Molecular Biology, Hairs & Fibers, and Paints & Polymers) as well as maintenance of certification in the disciplines of General Criminalistics and Biochemistry. At present, the ABC certifies over 1,000 scientists among these disciplines. Prospective applicants must first pass a credential review and then successfully challenge a written examination that assesses knowledge, skills, and abilities within the discipline. A more thorough description of this process is available at www.criminalistics.com.

This presentation describes post-examination reviews that the ABC Examination Committee uses to assess the efficacy of the examination process. Data collected in the examination process includes self-reported demographic information (e.g., education major, degree, years of experience, and hours devoted to study), examinee critiques, and examination scores. Examination scores are first correlated against the demographic information. Separately, test scores are used to monitor the performance of each examination over time and to compare the performance of different examinations.

Analysis of the demographic information clearly shows a positive correlation between the hours of study and a successful outcome for the test applicant. This review shows that within the independent examinations, the success rate is stable through time, while also demonstrating varying levels of difficulty between the individual examinations. For example, whereas each examination is based on a maximum score of 200, the Drug Analysis median test scores varied only two points (148 to 150) over the course of three versions of this examination over a seven-year period, while the difficulty between examinations is demonstrated by median test score values ranging from 133 for the Comprehensive Criminalistics Examination to 165 for the Paints & Polymers Examination.

The ABC Examination Committee reviews all of this data to monitor success rates of the applicants and performance of the examinations.

Certification, Criminalistics, ABC

B47 A Forensic Odyssey: When Doing the Right Thing Doesn't Always Lead to the Desired Result or Good Deeds Can Be Punished!

Barry A.J. Fisher, MS, MBA, 81620 Avenida Estuco, Indio, CA 92203*

After attending this presentation, attendees will better understand unintended consequences of ethical conduct in a crime lab setting.

This presentation will impact the forensic science community by providing attendees with a possible reaction when an employee stands up to do what is right and faces the consequences. It will also suggest ways to both act and to not be punished for reporting the deed.

In the early 1990s, it was determined that a drug chemist was “dry-labbing” drug testing results in the laboratory. The criminalist would run an analysis at the start of her shift and subsequently select cases that contained the same drug as determined by a presumptive test run by officers. She then used the same Infrared (IR) spectrum for each subsequent analysis but changed the annotation on the printout to correspond to each case she reported out. She ultimately claimed that she followed procedure and ran each case separately; however, running IR spectra ½ minute apart seemed to belie that explanation.

The analyst's supervisor discovered the ruse. He happened to have her day's work piled on his desk with each of the IR spectra visible. He was surprised to see how closely they matched up and, out of curiosity, held the printed spectra over a light box. They all registered identically. The analyst's supervisor immediately proceeded with his direct supervisor to discuss what he had discovered with the laboratory director.

Knowing this might become a criminal matter, laboratory management went to the sheriff's department's Internal Affairs Bureau to report the matter and did not interview the employee. The employee was relieved of duty, with pay, and ordered to remain at home during the investigation. The matter was referred to the district attorney's office for further investigation and possible prosecution. The employee, who had an MS degree in chemistry, claimed that she had not been properly trained on the lab equipment. Eventually the district attorney decided not to prosecute (they thought the matter was too arcane and a jury would not understand the issues). The analyst was subsequently discharged from the sheriff's department.

Once laboratory management determined that this situation existed, the evidence from all cases the analyst had examined was ordered back and a neighboring crime laboratory was asked to reexamine the cases. At the same time, laboratory management also recalled a sampling of other criminalists' drug testing cases. All reported results, without exception, turned out to be correct.

The laboratory reported the incident and the remediation to their accrediting body, the American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB). In addition, the district attorney's office notified the local defense bar of the matter. At the conclusion of this, the manager felt the laboratory had done the right thing and the matter had sorted itself out.

To much surprise, a department investigation was ordered and the manager's behavior became its focus. The theory was that this whole thing should never have happened if the manager had been more attentive. After months of interviews with every employee at the lab and an Internal Affairs investigation with the manager as the subject, he was found wanting and demoted. The sheriff's department allowed the manager to keep his job title and salary; however, the manager now reported to a captain who was the defacto crime lab director, with the manager as the figurehead. The manager was also given ten days leave without pay. In addition, the manager was told that if he chose to fight these sanctions, he would be terminated. He decided to take his punishment. Naturally, the manager was pretty depressed over the whole business. The depression took him five years to get over!

The lessons the manager learned from this incident were: (1) if you honestly feel you are in the “right,” you should fight back and use all the remedies at your disposal, including hiring a lawyer to represent you and, if necessary, civil litigation; (2) keep detailed records of everything leading up to the event and, for that matter, all you do as a manager or supervisor. Remember the admonition: if it's not in writing, it never happened; (3) be wary about being a civilian in a police environment. The manager's experience was that civilians were treated differently. He saw this firsthand a few years later when one of the lab's firearms examiners failed a proficiency test. Initially the laboratory recalled some of the firearms examiner's work and found other mistakes. Ultimately, the laboratory had to

Criminalistics Section - 2015

review some 200 of the firearms examiner's cases, mostly homicides. The captain in charge of the lab at the time was never chastised in the slightest for this event that occurred on his watch; (4) there is an unfortunate tendency to sometimes "throw someone under the bus" as penance for an act. A word to the wise: make sure it's not you!; and, (5) if it happened again, the he would still do the right thing and report the misdeed as he did.

Ethics, Whistle Blowing, Ethical Payback

B48 Deconvolution: An Automated Means of Unknown Identification in the Criminalistics Lab

Sarah A. Keeling, MS, 3855 Blair Mill Road, Apt 235-N, Horsham, PA 19044*

After attending this presentation, attendees will have a fundamental understanding of the benefits of using deconvolution.

This presentation will impact the forensic science community by allowing for more objective and efficient analysis of data. It will incorporate retention time, providing better matches to compounds in the target database.

Traditional means of identification in a forensic chemistry laboratory has been Gas Chromatography/Mass Spectrometry (GC/MS) using routine library search methods. The task of identifying drugs of abuse has become more challenging due to their increased diversity. There has been a proliferation of new psychoactive substances including the “bath-salts” and synthetic cannabinoids. In order to circumvent **Drug Enforcement Administration** (DEA) scheduling, illicit manufacturers of these compounds continually alter the molecules slightly, giving rise to a class of compounds with many structural similarities. The mass spectral similarity of these molecules can lead to misidentification using traditional library searching procedures. In addition to the growing list of drugs, many samples are complex mixtures containing active and inactive constituents (i.e., synthetic cannabinoid mixtures sprayed onto a botanical matrix). The chromatograms require additional manual manipulation to confirm the presence of these drugs, which can be subjective and time consuming. Trace amounts in these complex mixtures can be missed. Chemists must properly identify isomers and analogs of new compounds. In order to properly distinguish the closely related forms of these molecules, precise retention time measurements are required.

To maintain this precise control over retention time of the drugs, Retention Time Locking (RTL) is used. Deconvolution Reporting Software (DRS) is an automated and objective means of analyzing chromatographic data using the Automated Mass Spectral Deconvolution Identification System (AMDIS) -searching algorithm and Agilent® Chemstation®. The software analyzes extracted ion chromatograms for each mass throughout the entire chromatogram. Using the shape and apex of the chromatographic peak, masses are assigned to a specific component. This produces superior cleaned spectra compared to data processing using traditional searching algorithms. Coupled with retention time locking, DRS is able to generate match factors based not only on the cleaned mass spectrum, but also the expected retention time of analytes from the target compound library. Even with interferences and coelution, the process is capable of identifying trace components.

A database was built in-house under retention time locked conditions containing both traditional drugs of abuse and newer novel psychoactive substances. DRS was applied to multiple chromatographic situations encountered in real case work. Comparison data was generated for 550 drug identification cases, encompassing 1,757 findings and representing 131 individual drugs. These samples were processed using DRS and traditional data processing methods. These cases included five different scenarios: simple single component data, column overloads, trace amounts, samples with interferences/coelutions, and compounds with similar mass spectra. After the comparison study, DRS was implemented as the primary means of data analysis in the laboratory. Cases processed included samples that contain traces of fentanyl in heroin, coeluting peaks that share many of the same fragments (THC and hydrocodone), psilocin in mushroom samples, and specific isomeric determinations (2-Methylethcathinone (MEC), 3-MEC, and 4-MEC).

Because of retention time locking, the data generated from multiple instruments had virtually identical retention times, eliminating the need to run standards along with the case samples suspected to contain isomers and allowing the in-house library to be used on all instruments in the laboratory and at remote sites. DRS consistently identified components in multiple chromatographic scenarios. In the majority of cases, manual data processing yielded the same results as DRS; however, the time and level of experience necessary to make the identification via traditional data processing was far greater than that needed for DRS. In approximately 40 instances, traditional means failed to identify trace components in a sample whereas DRS properly identified these analytes. DRS is an automated, objective tool that was found to be more efficient and reliable for processing GC/MS data.

Deconvolution, GC/MS Data Processing, Retention Time Locking

B49 Chemometrics Applied to Spectral Comparison in 2D Raman Mapping

Gary H. Naisbitt, PhD*, Utah Valley University, Criminal Justice Dept, MS 286, 800 W University Parkway, Orem, UT 84058; Marcyne Blythe, Utah Valley University, Criminal Justice Dept, MS 126, 800 W University Parkway, Orem, UT 84058; Benjamin Little, Utah Valley University, Criminal Justice Dept, MS 126, 800 W University Parkway, Orem, UT 84058; and Joshua B. Harris, Utah Valley University, Criminal Justice Dept, MS 126, 800 W University Parkway, Orem, UT 84097

After attending this presentation, attendees will understand this demonstration of applying multivariate statistical methods available in Renishaw® WiRE™ 3.41 to interpret and validate Raman mapping data.

This presentation will impact the forensic science community by demonstrating the importance of the use of orthogonal statistical methodologies to corroborate analytical conclusions.

Chemometrics concerns the extraction of relevant information from chemical data by mathematical and statistical tools. Chemometric methods rely on a wide variety of multivariate operations that are applied to chemical spectral data to separate noise from information, compare and classify spectra, and validate both methodology and conclusions. Although routinely applied in academic and research settings, crime laboratories do not routinely use chemometrics.

This study uses different statistical methods that are part of the instrument software to quickly verify and validate conclusions without using separate statistical software. Such orthogonal crosschecks add strength to analytical decisions with minimal additional effort.

Maps are 2D arrays composed of rows of locations called cells. The process is much the same as digital photography in which each cell is called a pixel. In both, each location contains information for that location and in the case of the mapped cell, the information is both photographic and spectral. After data collection, the spectrum in each cell is identified by the statistical operations below and is assigned a false color for identification. The map is then redrawn using the false colors showing the location of the chemical components.

Mapping is particularly important in trace material analysis where the distribution and size of individual components are important identifying characteristics that can only be assessed by mapping the sample. Polymer identification, counterfeit pharmaceutical products, and ink location in altered documents are conventional forensic applications. Non-mapping analysis determines only a single or a small number of locations that, due to micro-heterogeneity, can lead to false identification. Mapping analysis corrects that deficiency.

Raman spectra were determined with a Renishaw® inVia Raman microscope equipped with a motorized stage and the data were analyzed using Direct Classical Least Squares component analysis (DCLS), Principle Component Analysis (PCA) and Multivariate Curve Resolution (MCR) techniques available in Renishaw's® WiRE® 3.4 instrument software.¹ The mapped data were evaluated by the three statistical methods with the goals of correct spectral assignment and validation of one method by agreement with another.

The key to mapping analysis is the ability to accurately identify the spectral information in each cell. DCLS relies on reference spectra for comparison and applies least squares analysis to compare the unknown spectrum to the reference spectra. MCR/Alternate Light Source (ALS) does not rely on reference spectra for comparison but is able to extract component spectra from the data of a mixture. Usually, at least a single component of the mixture must produce a strong enough response to be unambiguously identified for this method to work. PCA does not produce spectral data but reorganizes the data into groups (principle components) that account for the greatest variation. As such, PCA is often used to eliminate noise and sort spectra into groups containing the same properties.

The presentation will include tables and colored maps that compare the statistical results.

Raman Mapping, Chemometric, Spectral Comparison

B50 Effectiveness of Zar-Pro™ Fluorescent Blood Lifting Strips

Corinne E. Martin, BS*, 8070 Woods Highway, Whitesboro, NY 13492; and Peter Massey, MS, University of New Haven, 300 Boston Post Road, West Haven, CT 06516

After attending this presentation, attendees will be better informed about Zar-Pro™ fluorescent blood lifting strips and which surfaces obtained an effective and detailed lift of a bloody fingerprint impression. Attendees will also learn if the amount of dilution affects the degree of fluorescence produced by the lifting strip when visualized with an Alternate Light Source (ALS).

This presentation will impact the forensic science community by introducing a simple, cost-effective tool to lift bloody fingerprints, especially from immovable objects at a scene. Also, the fluorescence enhances ridge details of the lifted print to provide a permanent identification comparison.

Many times at a crime scene, objects with bloody impressions on them have to be removed and brought back to the laboratory and processed using chemical techniques. This can sometimes be onerous and difficult if the object is large and immovable. Jessica Zarate's invention of the fluorescent blood-lifting strips allow for bloody impressions to be lifted and preserved from virtually any surface. Zarate developed a chemical formula which has a high binding power with proteins, added a photo fixative, and bound it to a nylon transfer membrane. The photo fixative allows the prints to be preserved without being altered or smudged. Titanium dioxide has only been tested for the last ten years but has been found to be a non-toxic alternative that can be used on fingerprint impressions. These lifting strips provide a non-toxic fluorogenic method for lifting bloody impression evidence. The fluorogenic properties are a product of metal-enhanced fluorescence and don't require additional chemicals. The fluorescence is produced by blood proteins and other proteinaceous secretions, which contain intrinsic fluorophores when excited with an ALS. These strips were developed to create an easy-to-use, portable, non-toxic method for lifting, enhancing, and preserving bloody impressions, with the intent of being universally accepted. They are both durable and affordable for law enforcement agencies with minimal training needed. The entire process only takes minutes, cutting out numerous chemicals and time-consuming multi-step procedures. The major advantage is that they are preserved in a non-perishable form until ready to be used.¹

In this study, the materials being tested were hardwood floors, 2x4s (unfinished wood), brick, granite counter top, and unpainted drywall. This study used human blood and pig blood to test if there is a difference in the results of ridge detail or fluorescence with the lifting strips. In addition, this study tested dilutions of the blood to determine if there are limitations of visualization on the lifting strips (undiluted, 1/10, 1/100, and 1/1,000). For deposition, the subject's finger was held in a horizontal position with approximately ten microliters of blood placed on the thumb. The dry time on the subject's finger before deposition on a test surface ranged from 20 to 50 seconds, timed using a digital stopwatch. After deposition on the substrate, the bloody impression was left to dry for one hour before use of a lifting strip. The strips were then activated according to manufacturer's instructions. After the lifting strip was used, it was viewed with the CrimeScope® ALS using the 455nm filter with an orange barrier filter. Photographs were taken using a Canon® EOS® Rebel T5i EF-S after deposition, after lifting, and after fluorescence to ensure proper documentation of the process.

Data shows that the lifting strips produced a full print with significant identifying ridge details. The experiment also showed that fluorescence occurs with undiluted blood, although the blood did quench the fluorescence in some cases. The dilution series was used to test the limit of detection of the strips. For treated hardwood samples, fluorescence occurred down to the 1:10 dilution for both human and pig blood, whereas for untreated pine, fluorescence occurred down to the 1:10 dilution for both blood sources, but it did not fluoresce for undiluted human blood. In comparison, for lifting strips used on polished granite, fluorescence was seen down to the 1:10 dilution for both blood sources. Lifting strips used on masonry bricks showed fluorescence at the 1:10 dilution but not for undiluted blood. For lifting strips used on unpainted drywall, undiluted human blood did not fluoresce but fluorescence was noted for all other blood sources down to the 1:10 dilution. Overall, there was no difference or change in fluorescence by source of blood tested.

Blood, Fingerprints, Fluorescence

B51 An Analytical Profile of 2-[(2,6-dichlorophenyl)-amino]phenylacetoxyacetic Acid (Aceclofenac)

Michael White, BS, 99 10th Avenue, New York, NY 10011*

After attending this presentation, attendees will be able to identify aceclofenac encountered in both illicit and licit preparations.

This presentation will impact the forensic science community by explaining how, in this time of tight budgets and increasing turnaround times, this data can assist in the identification of aceclofenac in both licit and illicit samples in lieu of purchasing a standard, thus saving the forensic community not only time but also money.

Structurally, aceclofenac is a phenylacetic acid derivative and classified as a Non-Steroidal Anti-Inflammatory Drug (NSAID) with analgesic properties.¹ According to Saraf, aceclofenac is a potent prostaglandin inhibitor through the inhibition of the enzyme cyclooxygenase.² The analysis and identification of 2-[(2,6-dichlorophenyl)-amino]phenylacetoxyacetic acid commonly referred to as aceclofenac is discussed. Through the course of routine analysis, it became apparent that the Electron Ionization (EI) mass spectrum of aceclofenac was similar to diclofenac and could be difficult to differentiate using Gas Chromatography/Mass Spectrometry (GC/MS) alone. After an exhaustive search, it was determined that there was a lack of forensically relevant data available to make an identification. This analytical profile is intended to fill this need. The following techniques were chosen to represent a wide range of instrumental techniques utilized in forensic laboratories to include Ultra High-Performance Liquid Chromatography/Quadrupole-Time-of-Flight/Mass Spectrometry (UHPLC/QTOF/MS), Liquid Chromatography with Tandem Mass Spectrometry (LC/MS/MS), Liquid Chromatography/Mass Spectrometry (LC/MS), Gas Chromatography/Mass Spectrometry (GC/MS), Fourier Transform Infrared/Attenuated Total Reflectance (FTIR/ATR) spectroscopy, and Nuclear Magnetic Resonance (NMR) spectroscopy.

Through the use of the various instrumental techniques mentioned above, it was determined that an effective analytical approach for the identification of aceclofenac in both licit and illicit samples is LC/MS/MS, LC/MS, and NMR. Depending on the purity of the sample, FTIR/ATR is also a viable test for identifying aceclofenac. Through the use of these instrumental techniques, it is possible to confirm the presence of aceclofenac in unknown drug samples.

After attending this presentation, attendees will learn how a new isothermal amplification method can be applied to mRNA profiling for the identification of forensically relevant biological fluids and tissues.

This presentation will impact the forensic science community by presenting possible alternatives to how mRNA profiling assays are performed and how these new methods may be more amenable to on-site analysis at crime scenes.

Conventional body fluid identification methods are often costly, not only in terms of time and labor required for their completion but also in the amount of sample consumed. Additionally, while methods are available for the identification of human blood and semen, none of the routinely used serological and immunological tests can definitively identify the presence of human saliva, vaginal secretions, menstrual blood, or skin. Thus, attempts to develop molecular-based approaches to body fluid identification have been made in order to provide operational crime laboratories with significantly improved specificity and sensitivity. The use of messenger RNA (mRNA) profiling has been proposed to supplant conventional methods for body fluid identification. It is based on the premise that each single tissue type is comprised of cells that have a unique transcriptome or gene expression profile. Currently, numerous biomarkers have been identified and validated for the identification of forensically relevant body fluids and tissues (blood, semen, saliva, vaginal secretions, and skin). Standard mRNA body fluid assays require laboratory equipment that is not meant to be used at crime scenes and requires hours to generate data. Thus, there is a need for the development of more rapid, simple, and inexpensive methods for mRNA profiling.

A potential alternative mRNA profiling strategy involves the use of LAMP. LAMP's advantages are primarily derived from its unique reaction mechanism. The amplification starts at 60°C to 65°C with primers annealing the target DNA strand and self-priming to form dumbbell-shaped structures that will be used in the strand displacement amplification. In this way, the primers can continuously prime, extend, and displace on their own amplicons. For the detection of RNA targets, LAMP can be combined with Reverse Transcriptase (RT-LAMP) in a single mix. The reaction can produce large quantities of DNA (up to 10⁹ copies in under an hour), enabling naked-eye detection of amplicons with suitable colorimetric or turbidometric sensors. Product detection without aperture of the reaction tube diminishes concerns about amplified product contamination of laboratory environments, a matter of constant vigilance with current detection schemes based on the Polymerase Chain Reaction (PCR).

Here a prototype rapid LAMP of mRNA biomarkers method for the identification of semen (PRM2, TGM4) and saliva (STATH, HTN3) is described. Based on initial testing, the developed 90-minute assays (one-step closed reaction from RT to detection) permit the identification of the body fluid origin of dried semen and saliva stains and demonstrate a high degree of reproducibility (technical and biological replicates). For semen, it was determined that PRM2 was the most suitable candidate. Semen was correctly identified in 8/10 known semen samples (one false negative, one vasectomized male donor so PRM2 was not expected or observed). Specificity was demonstrated with a failure to detect PRM2 (semen) in blood, saliva, vaginal secretions, menstrual blood, or skin samples (N=15) (separation in detection time of ~40 to 55 minutes). Reproducibility was assessed through an evaluation of ten donors (three technical replicates per donor). Semen was correctly identified in nine donors (10th donor was a vasectomized male and the observed standard deviation among individual donors was as little as 0.2-3.4 minutes). While more variability was observed for saliva due to the nature of the body fluid itself, saliva (STATH) was successfully identified in samples stored at room temperature for one to two years (N=4) and samples exposed to environmental insults (heat, light, humidity, and rain) for days to up to one month (N=17), with results comparable to a Capillary Electrophoresis (CE)-based mRNA profiling multiplex. Successful detection of saliva was achieved for 38% of the compromised and environmental samples using the STATH-LAMP assays compared to 31% successful detection of STATH using CE-based detection.

Criminalistics Section - 2015

The results from these initial studies indicate a possible utility of isothermal RT-LAMP assays for body fluid identification. The potential exists (and is the subject of current work) for the development of these assays on an integrated microfluidic device which would permit confirmatory body fluid identification by mRNA profiling at its point-of-use (crime scenes or in the biology screening laboratory).

Isothermal Amplification, RNA Profiling, Body Fluid Identification

B53 Determination of Gunshot Residue (GSR) in Vehicle Head Liners Using Scanning Electron Microscope (SEM)

Heather M. Hammond, BS, 3344 Lakeside Place, Hermitage, TN 37076*

After attending this presentation, attendees will understand some principles of Gunshot Residue (GSR) collection, the use of a Scanning Electron Microscope equipped with Energy Dispersive X-ray (SEM/EDX) for gunshot residue analysis, the potential for using a High-Efficiency Particulate Absorption (HEPA) filter/hand-held vacuum approach to collect GSR from vehicle head liners, and the feasibility of using this alternate collection method.

This presentation will impact the forensic science community by offering the possibility of augmenting current GSR collection from vehicles with the addition of a HEPA filter/hand-held vacuum methodology to collect GSR from any part of a vehicle. Identification of a practical approach for collecting GSR from vehicles could allow for faster and more accurate collection.

This study began as a continuation of a previous project that used the same collection methodology to recover GSR from hair. It was determined from this earlier project that this collection methodology could be a useful approach for collecting GSR evidence elsewhere. This experiment reinforces the methodology presented in this research as a means of reducing the amount of time spent processing surfaces for the presence of GSR.

The experiment consisted of the collection of GSR from ten different vehicles — five with the firearm discharged inside the vehicle and five with the firearm discharged one foot distance outside the vehicle from the passenger-side window. The firearm in all instances was discharged perpendicular to the long axis of the open car window. Each vehicle was divided into eight sections for collection. The eight sections were the Driver-Side Front Head Liner (DFH), Driver-Side Front (DF) that consisted of everything except the head liner, Passenger-Side Front Head Liner (PFH), Passenger-Side Front (PF) that consisted of everything except the head liner, Driver-Side Rear Head Liner (DRH), Driver-Side Rear (DR) that consisted of everything except the head liner, Passenger-Side Rear Head Liner (PRH), and Passenger-Side Rear (PR) that consisted of everything except the head liner. For this project, the sections of the vehicles labeled PFH were analyzed. The collection method included a hand-held vacuum with a HEPA filter and GSR stubs. The GSR stubs were manually analyzed at 500x using a horizontal method that covered the width of the stub. This was done in a single pass using SEM/EDX.

Analysis of the passenger head liner from firing inside the vehicle showed a success rate of greater than 20% of the particles scanned and from firing outside the vehicle, a success rate of 10%-15%. The success rate was based on a particular particle containing lead, barium, and antimony (Pb-Ba-Sb). Pb-Ba-Sb is such a unique particle that, when found, can directly be connected to GSR. The collected results suggest that using this alternate collection method could aid greatly in the time spent on collecting evidence from vehicles. Firing from completely inside the vehicle resulted in more GSR being recovered than from firearms discharged outside the vehicle.

The results further indicate that it is feasible to detect gunshot residue from vehicle head liners using a HEPA filter and a vacuum. The HEPA filter must screen for particles as small as 1-10 μ m. The filters used in this experiment screened for particles as small as 0.3 μ m. Because portability is a necessary requirement for crime scene equipment, the vacuum used was a rechargeable hand-held model that had been proven previously to have enough power to gather GSR particles from hair. The significance of these results show that this alternate collection methodology can be a useful tool for crime scene investigators.

Gunshot Primer Residue, Vehicles, SEM/EDX

B54 Forensic Examination of Oriented Polymer Films: Polarized Light Examinations of Packaging and Shipping Tapes

Walter F. Rowe, PhD, George Washington University, Dept of Forensic Science, 2100 Foxhall Road, NW, Washington, DC 20007; and Karen Brensinger, BS, George Washington University, Dept of Forensic Sciences, 2100 Foxhall Road, NW, Washington, DC 20007*

After attending this presentation, attendees will understand the nature of mon-axially and bi-axially oriented polypropylene polymer films, which are widely used in the manufacture of packaging, shipping, mailing, and moving tapes. Attendees will also understand the role that polarized light microscopy can play in the forensic analysis of such polymer films. Attendees will understand the potential for the application of digital photomicrography and digital image analysis to the forensic analysis of polymer films in commercial products such as packaging, shipping, mailing, or moving tapes.

This presentation will impact the forensic science community by emphasizing the continuing value of simple analytical tools such as polarized light microscopy, particularly when this tool is enhanced with digital photography and digital image analysis.

Because polymer films produced commercially are typically composed of polyethylene, polypropylene, or polyesters, Infrared Spectrometry (IR) has limited utility for making brand identifications. The physical characteristics of these films may be more useful in making such identifications. Amorphous polymer films are optically isotropic and appear dark at all orientations between crossed polarizing filters. On the other hand, crystalline films may have up to three indices of refraction: one parallel to the direction of extrusion of the film (sometimes called the machine direction), one perpendicular to the machine direction in the plane of the film, and a third perpendicular to the film plane. Crystalline films are birefringent; they will also show classic bi-axial interference figures.

Commercial tape products variously designated packaging, shipping, mailing or moving tapes are frequently made of polypropylene films. During manufacture, the film may be stretched only in the machine direction, resulting in a Mono-Axially Oriented Polypropylene (MOPP) film; if the film is also stretched perpendicular to the machine direction, the result is a Bi-Axially Oriented Polypropylene (BOPP) film. Both MOPP and BOPP tapes are birefringent; however, when specimens of BOPP tapes are examined with a polarizing microscope and are rotated slightly away from extinction, they display crosshatched patterns.

This research explored the application of digital photomicrography and digital image processing to the forensic examination of packaging tapes. Seventeen samples of 5cm (two inch) nominal width clear packaging tape, representing seven different brands, were examined. Small strips were cut from each tape sample and mounted on microscope slides directly, using the tapes' adhesives. Care was taken to retain at least one machine edge. Slide mounts were also prepared by stripping the adhesive from the tape backing using a mixture of xylenes. Again, small strips were cut from each tape sample, care being taken again to keep one machine edge intact. The adhesive layers were removed to facilitate thickness measurements of the tape backing. Thickness measurements were made in triplicate on each cleaned strip of tape using a calibrated digital caliper. Finally, the cleaned strips of tape backing were mounted in a medium having $n_D=1.54$. Each slide was viewed under a polarized light microscope equipped with a ten-megapixel digital camera. Digital photomicrographs of the tape samples were taken: (1) at maximum birefringence; (2) at extinction; and, (3) just past extinction to display the crosshatched patterns characteristic of BOPP polymer films. The tapes' extinction angles (defined as the smallest angle between the machine edge of the tape when it is at extinction and an analyzer or polarizer direction) were measured using the camera's software. The discrete 2D Fourier transform was applied to the digital images of the crosshatched patterns of the BOPP tapes.

The thicknesses of the tape backings provided little discrimination among samples; however, different brands of tape often showed different interference colors, even when the thicknesses of the backings were the same. Rolls of the same brand and type of tape could sometimes be differentiated by differences in interference colors. The extinction angles of the tapes varied from 0° (parallel extinction) to 13.5° . There were differences between brands but also between rolls of the same brand and type of tape. The crosshatched patterns of the BOPP tapes consisted of mosaics of diamond shapes. The diamonds differed in size and in the angles made by their sides. Several different types of crosshatched patterns were found. The discrete 2D Fourier transforms of the crosshatched patterns provided a simple method for comparing the crosshatched patterns.

Polarized Light Microscopy, Polymer Films, Fourier Transform

B55 Weight Measurements in the Forensic Chemistry Laboratory: A Surrogate Weight Study

Sandra E. Rodriguez-Cruz, PhD, Drug Enforcement Admin, Southwest Laboratory, 2815 Scott Street, Vista, CA 92081*

After attending this presentation, attendees will better understand the importance of weighing processes in the laboratory.

This presentation will impact the forensic science community by demonstrating the advantages of implementing a surrogate weight program for monitoring the performance of laboratory balances.

Analysis of controlled substances in the forensic chemistry laboratory involves both qualitative and quantitative measurements. Although final identification of the main psychoactive component(s) is often the final goal of many analytical schemes, some laboratories also provide customers with purity determinations, as well as adulterant and salt-form identifications, if needed based on jurisdictional requirements; however, there is one very relevant quantitative test that is performed by every law enforcement laboratory, regardless of its jurisdiction: the determination of the net weight of a substance. That is, the measurement of the amount of powder, plant material, liquid, etc. present in a particular piece of evidence.

Seized-drug weight determinations are important laboratory measurements that have direct effect on the judicial process. The net weight of material seized is often the very factor that determines a controlled substance felony level. Therefore, forensic chemistry laboratories should have well-established procedures for the appropriate procurement, maintenance, verification, and utilization of laboratory scales and balances. These procedures should include, at minimum, annual calibration by an external entity and a documented program for the routine maintenance and performance verification of balances. The use of weight standards (reference weights) must also be part of a balance verification program as it provides the traceability necessary for all weight measurements performed.

However, monitoring the performance of a weight measuring apparatus using standard reference weights may not provide a full picture of the weight measurement process. Standard weights are ideal for monitoring balance properties such as linearity, accuracy, and eccentricity; however, they are not expected to represent routine laboratory weighing processes where the buoyancy and density of the materials being tested can drastically differ from those of a standard reference weight. Controlled substance laboratory submissions are often irregularly shaped and submitted in plastic bags, buckets, bottles, etc. Weight measurements for these materials are therefore expected to be affected by multiple factors that may not be accounted for using standard reference weights.

This study presents the use of surrogate weights to monitor the variability of laboratory weight measurements over an extended period of time. Surrogate weights are made of plastic beads in flexible, clear plastic, heat-sealed bags that were barcoded for identification purposes. Surrogate weights were prepared (representing four different sizes) and are currently being used to monitor a total of 33 laboratory balances. Balances with readability of 0.1g, 0.01g, 0.001g, and 0.00001g are monitored using surrogate weights of 1,000g, 500g, 100g, and 40g, respectively. Surrogate weight measurements are performed once a day and have been on-going since December 2013. The data is collected and statistically analyzed to obtain the standard deviation of measurements for each balance being monitored. This provides a quantitative measure of the variability of weight results over an extended time period, supplementing the balance verification data obtained using standard reference weights.

Criminalistics Section - 2015

This presentation will summarize the results of this surrogate weight study. Calculated standard deviation values will be used to calculate minimum weight thresholds and to suggest acceptance performance criteria for each type of balance. This study will also provide a better understanding of the uncertainty of measurement associated with surrogate weights as representatives of routine weight measurements in the forensic laboratory.

Weight Measurements, Controlled Substances, Measurement Uncertainty

B56 Infrared Microspectroscopy for the Analysis of Nail Polish

Ashley K. Jackson, BS, West Chester University, 4668 Mercer Pike, Cochran, PA 16314; and Monica Joshi-Kumar, PhD*, West Chester University, Dept of Chemistry, Schmucker Science South, 750 S Church Street, West Chester, PA 19383

After attending this presentation, attendees will be able to discuss and evaluate the application of infrared microspectroscopy for the analysis of various types of nail polish.

This presentation will impact the forensic science community by informing examiners of: (1) the microscopic and spectroscopic differences between two visibly similar nail polish chips and other cosmetic smears that may be encountered as trace evidence; (2) the spectroscopic differences between classic and novel nail polish formulations; and, (3) the changes that impact comparative analysis of nail polish chips on exposure to various environmental conditions.

Coloring products are the mainstay of the cosmetic industry. These include products such as lipsticks, foundations, eye products, and nail polishes. Market research reports indicate that nail polish products have had record-breaking growth in recent years, spurred by celebrity endorsements. With the ubiquity of nail polish, it is highly likely that it would be encountered as evidence in a crime scene. As trace evidence, it may be encountered in the form of small chips, smears, and as coatings on a broken nail.

Nail polishes are pigmented coatings that are used to cosmetically enhance the appearance of toenails and fingernails. A typical nail polish is composed of film-formers, adhesive polymers, plasticizers, pigments, and other additives to add desired properties to the finished product. Nitrocellulose is the most common film-forming polymer used in the nail polish industry. Other film-formers include polycondensates of adipic acid, neopentyl glycol, and trimellitic anhydride or a styrene-acrylate copolymer. Tosylamide formaldehyde resin is a common adhesive polymer that is used. Plasticizers such as dibutyl phthalate, camphor, and citric acid resins are added to enhance the stability and flexibility of the polymers. Pigments could be either inorganic or organic pigments. Glitter particles are also added to some formulations to improve the shine of the cured product. All of these components and other curing and Ultraviolet (UV)-stabilizing additives are suspended in solvent with good drying properties. Examples of solvents include toluene, ethyl acetate, isopropyl acetate, isopropyl alcohol, methyl, and ethylacetone. Newer nail polish formulations are moving away from phthalates, toluene, formaldehyde, and other traditional components due to their toxic health effects. Three categories of novel formulations have invaded the market in recent years: water-based nail polish, 5-free nail polish, and 3-free nail polish. The water-based nail polish formulations use water instead of the above-listed solvents and sometimes use styrene-acrylate copolymers instead of nitrocellulose. The 5-free products do not include formaldehyde, formaldehyde resin, dibutyl phthalate, toluene, or camphor. The 3-free products eliminate dibutylphthalate, toluene, and formaldehyde.

The goal of this study was to characterize nail polish based on its microscopic and spectroscopic features using an infrared microscope. The development of an analytical method to conduct comparative analysis of nail polish chips is described. The method uses a germanium crystal Attenuated Total Reflectance (ATR) accessory for analysis of the samples. The surface area analyzed is 20x20 μ m and the sensitivity is greatly enhanced using a cooled Mercury Cadmium Telluride (MCT) detector. This study includes 12 brands of classic nail polish formulations. Each brand further includes multiple finishes. The microscope images are analyzed for particle size in products that have glitter and this information is combined with the spectroscopic information across the surface of the chip. Minor spectroscopic changes that occurred during storage of the smears and chips led to further study of environmental effects. In the classic formulations, the absorption peaks for nitrocellulose and tosylamide/formaldehyde resin dominate. The spectroscopic properties of the three novel formulations of nail polish described above have been studied. A color theme was selected and two products from each of the three categories were studied. This presentation includes Principal Component Analysis (PCA) and Discriminant Analysis (DA) of the data obtained for the various nail polish brands.

B57 Mathematical Modeling of Evaporated Petroleum Distillate Standards

Rebecca J. Brehe, BS, 1547 N Hagadorn Road, Apt 25, East Lansing, MI 48823; John W. McIlroy, PhD, Michigan State University, Chemistry Bldg, East Lansing, MI 48824; Ruth Waddell Smith, PhD, Michigan State University, School of Criminal Justice, 560 Baker Hall, East Lansing, MI 48824; and Victoria L. McGuffin, PhD, Michigan State University, Dept of Chemistry, East Lansing, MI 48824-1322*

After attending this presentation, attendees will be familiar with a mathematical model that can be used to generate chromatograms corresponding to different evaporation levels of petroleum distillate standards. These chromatograms can be included in reference collections that are currently used in the analysis of fire debris to determine the presence of an ignitable liquid in a submitted sample.

This presentation will impact the forensic science community by mathematically modeling chromatograms for different evaporation levels of petroleum distillate standards based on the original, unevaporated standard, with no additional experimental measurement necessary.

Fire debris samples are typically analyzed by Gas Chromatography/Mass Spectrometry (GC/MS) and the resulting chromatograms are compared to a reference collection of ignitable liquid standards to identify any liquid in the debris samples. Reference collections include chromatograms of ignitable liquids representative of the chemical classes defined by American Society for Testing and Materials (ASTM) International, as well as chromatograms of the liquid standards evaporated to different levels; however, evaporating liquids to a range of different volumes or masses can be time consuming and it may not be practical to generate evaporated counterparts for every liquid in the reference collection.

In this research, a mathematical model was used to generate chromatograms corresponding to different evaporation levels for a range of petroleum distillate reference standards. The utility of the model was investigated by comparing chromatograms of experimentally obtained evaporated petroleum distillate reference standards to chromatograms derived theoretically using the model.

For the experimentally obtained data, several petroleum distillate reference standards, including torch fuel, lamp oil, and kerosene, were evaporated to various levels under nitrogen, and the volume and mass remaining at each evaporation level was recorded. All unevaporated and evaporated liquids were subsequently analyzed by GC/MS and retention indices were calculated for all compounds in each chromatogram.

The mathematical model was then applied to the chromatographic data for the unevaporated petroleum distillate standards. The model predicts evaporation rate constants for compounds in each standard as a function of retention index. The determined rate constants were used to predict the fraction of individual compounds remaining, which ranges from one to zero, where one indicates no evaporation and zero indicates complete evaporation. The distribution of compounds determined using the model was then plotted versus retention index to generate chromatograms corresponding to the different evaporation levels.

Chromatograms derived theoretically using the model were compared to the experimentally derived chromatograms using Pearson Product-Moment Correlation (PPMC) coefficients, which offer a side-by-side comparison of all variables in the two chromatograms. Coefficients range from ± 1 to 0, with coefficients greater than ± 0.8 indicating strong correlation. For these data, PPMC coefficients indicated strong correlation ($r > 0.95$) between the theoretically derived chromatogram and the corresponding chromatogram obtained experimentally for each evaporation level.

This presentation will demonstrate the utility of the mathematical model to generate chromatograms representative of evaporated petroleum distillate standards based only on the unevaporated standard. Modification of the model to improve correlation between the theoretically derived and experimentally obtained chromatograms will be discussed, as well as further applications of the model.

Fire Debris Analysis, Evaporation, Mathematical Model

B58 Use and Detection of Ribosomal Inactivating Proteins (RIPs) as Surrogates for Active Toxins Via Immuno-Precipitation and Matrix-Assisted Laser Desorption-Ionization Time-of-Flight Mass Spectrometry (MALDI-TOF/MS)

Jessica M. Goss, MS, Spotsylvania, VA; James M. Robertson, PhD, CFSRU, FBI Laboratory, 2501 Investigation Parkway, Quantico, VA 22135; and Jason D. Bannan, PhD, Laboratory Division, 2501 Investigation Parkway, Quantico, VA 22135*

After attending this presentation, attendees will understand the forensic issues associated with Ribosomal Inactivating Proteins (RIP), the purpose of a surrogate for validation of detection assays, and the significance of detection using immune-precipitation and Matrix-Assisted Laser Desorption/Ionization-Time-Of-Flight/Mass Spectrometry (MALDI-TOF/MS).

This presentation will impact the forensic science community by providing a rapid, cost-effective, and sensitive method for the detection of RIP in various food matrices thought to be targets during a biocrime. Due to RIP toxins' lethality, availability, ease of isolation, and lack of treatment, there is a critical need for continued development of RIP countermeasures.

Naturally produced RIPs, such as ricin and saporin, can be highly lethal when ingested. Due to the availability or ease of production of these toxins, their use is attractive in the commissioning of a biocrime or use as a tactical bioweapon. Therefore, it is necessary to test complex matrices, such as food or drink, for protein toxins in a rapid, cost-effective manner. Researchers have developed an MS-based assay that involves capture of ricin from milk, apple juice, serum, and saliva using magnetic beads and testing of the toxin's enzymatic activity; however, many protein toxins are tightly regulated select agents making it difficult for many laboratories to test new methodologies or perform basic research. A surrogate, non-toxic protein that works in the immuno-capture step and mimics ricin's activity should be capable of use in validating the detection assay with additional matrices in order to test the effects of pH and viscosity. If successful with ricin, this approach could be used to safely test variety of toxins for adulteration of different food stuffs and drinks.

The first goal of this study was to demonstrate the efficacy of a surrogate protein as a toxin substitute for validation and matrix testing. This study used a MALDI-TOF/MS assay developed by the Centers of Disease Control and Prevention (CDC) to test and optimize detection of a surrogate RIP protein, Uracil DNA Glycosylase (UNG). UNG, which removes a single uracil from an AUAT stem-loop, yields a similar DNA product as a RIP-II toxin, while by-passing the safety concerns of active, purified toxins. Next, the validity of this assay concept as a detection and activity method was confirmed by testing complex matrices with a wide pH range and texture complexity, such as a sports drink, ketchup, salad dressing, dry coffee creamer, mustard, and sweet potato and banana baby foods. Lastly, this study determined the lower Limit Of Detection (LOD) of this assay by reducing the UNG concentration in water.

AmpErase® UNG and its target substrate, ric12aUtA, proved suitable surrogates for ricin and its substrate target since this enzyme has similar RIP activity and DNA target as ricin. The cleaved substrate resulted in a loss of 94 Da, which was measured with MALDI-TOF/MS. Ratios of the cleaved product, corresponding to the m/z 3,535 peak, and the uncleaved product, seen at m/z 3,630, were used to estimate the efficiency of the process in the various matrices. A cleavage efficiency of $\geq 90\%$ was measured for water, the sports drink, ketchup, salad dressing, and coffee creamer. Very viscous matrices (mustard, sweet potato baby food, and banana baby food) had very low to zero cleavage efficiencies ($46.8 \pm 31.4\%$, $16.6 \pm 8.3\%$, and 0.0% , respectively). The LOD for this assay was reduced from 1-5 pmol (CDC's method) to 0.18-1.8 pmol of the surrogate per reaction. Various incubation times were also tested in an effort to optimize the assay when protein concentrations were very small. Overnight incubation of water was $32.1 \pm 0.01\%$ efficient, while three- to four-hour incubation was $10.7 \pm 0.01\%$ efficient. This indicates that a longer incubation time could be used when surrogate concentration is very low.

Ribosomal Inactivating Protein, MALDI-TOF, Validation

B59 A Static Collection Approach for Target Explosive Analog Odors

*Claudia L. Sanchez, BA**, 11200 SW 8th Street, Miami, FL 33199; *Adhly M. Huertas, BSc, Modesto A Maidique Campus (MMC)*, 11200 SW 8th Street CP344, Miami, FL 33199; *Paola A. Prada, PhD*, 11264 SW 128th Court, Miami, FL 33186; and *Kenneth G. Furton, PhD*, Florida International University, International Forensic Research Institute, University Park, Miami, FL 33199

After attending this presentation, attendees will understand: (1) some critical aspects of employing a passive collection method for the creation of potential canine training aids using real explosive as the odor source; (2) a longevity study of target explosive odorants from such training aids; and, (3) practical field testing using certified canine explosive teams.

This presentation will impact the forensic science community by serving as a feasibility study of efficient canine training-aid creation through novel non-contact passive procedures that can augment the practical applications of enhanced canine training and use in military operations.

Currently, there are many training aids being used for explosives detection canines; however, to date, a superior form of an explosive training aid has not been created that effectively mimics the evolving variety or ordnance encountered in the battlefield. For this reason, the development of a training aid suitable for the explosive encountered in daily military operations is necessary to provide effective canine explosive detection, as the use of sniffer dogs has proven to be a reliable tool for the rapid detection of volatile explosive vapors. In practical field operations, an imperative need is to be able to collect target explosive material in a rapid and safe manner. The creation of such aids is not only useful during criminal investigations at pre- and post-blast sites but also critical for further optimized training of explosive canine teams who need to be exposed to the evolving range of explosive material being used in the military arena. The goal of this research is to present a detailed evaluation of the static collection of target explosive analog odors for the creation of useful canine training aids from real explosive materials. Even though currently available training aids utilize synthetic chemicals mimicking the odors emanating from real explosives, this study investigates the feasibility of creating training aids using a passive collection methodology of target odorants using the real explosive as the odor source.

In this study, experiments were based on previously identified signature explosive odors such as 2-ethyl-1-hexanol, derived from plasticized explosives, 2,4-dinitrotoluene from single-based smokeless powder, and 2,3-Dimethyl-Dinitrobutane (DMNB), derived from taggants added to explosives. C-4 explosive material was used for the static collection of the 2-ethyl-1-hexanol and DMNB target odor signatures, as well as single-based smokeless powder for the collection of 2,4-dinitrotoluene. The samples were collected indoors (23.8°C with a relative humidity of 77.2%) with a 4"x4" cotton gauze pad as the collection material. All samples were stored in silanized 40ml glass vials. In order to obtain odorants profile, vials collected from C-4 explosive material were injected via Solid-Phase Microextraction (SPME) for 30 minutes at approximately 56°C and eventually analyzed by GC/MS and vials collected from single-base smokeless powder were injected via SPME for 21 hours at approximately 56°C and eventually analyzed by Gas Chromatograph/**Electron Capture Detector** (GC/ECD). A metal holder device was used to clamp the gauze pad at a distance of approximately two to three inches from the odor source (explosive material). A time optimization analysis was conducted for all three target odor signatures in time intervals of 0.5, 1, 5, 15, 30, 45, 60, 90, and 120 minutes. Samples were taken in triplicate for each of the selected time intervals and each trial was conducted on different days with a corresponding control sample to monitor for any possible background/contamination. According to the generated results, it has been shown that odor signatures such as 2-ethyl-1-hexanol can be collected at an optimal time of 15 minutes, with a collected mass of 82.7±7.75ng for the target odorant. The collection for the DMNB and 2,4-dinitrotoluene target odors showed an enhanced collection at 30 minutes of static exposure of the gauze pad, with a collected mass of 125±10.1ng and 5.05±0.51ng, respectively.

The results demonstrate the successful collection of target odor signature Volatile Organic Compounds (VOCs) from the real explosive as the odor source onto an absorbent material such as a gauze pad, which can then be consequently sealed and stored as a canine training aid. Other factors to be presented include how long the collected odor lasts after being stored and the efficacy of these stored static collected training aids for field use with certified explosive detection canines. Overall, the results demonstrate that it is possible to collect representative explosive odorants using a completely passive static collection procedure for the creation of reliable training aids via this non-contact passive approach which can aid in the development of effective canine team training.

Static Collection, Training Aid, Canine Detection

B60 Illicit Substance Volatile Organic Compounds (VOCs) Analysis for Canine Detection

Adhly M. Huertas, BSc, Modesto A Maidique Campus (MMC), 11200 SW 8th Street CP344, Miami, FL 33199; and Kenneth G. Furton, PhD, Florida International University, International Forensic Research Institute, University Park, Miami, FL 33199*

After attending this presentation, attendees will have a better understanding of an optimized analytical approach for the determination of the Volatile Organic Compounds' (VOCs') profile of a frequently trafficked illicit substance. The development of such a method will aid in improving the quality of information currently being used for canine training purposes.

This presentation will impact the forensic science community by providing a detailed overview of potential compounds that might serve as key constituents in the development of training aids. The development will likely ensure an improvement on the capability of detection of one of the most popular illicit substances by providing a reliable, cost-effective, and non-hazardous system.

Law enforcement agencies have put forth great effort toward stopping drug trafficking. Regardless, the trafficking and use of illicit substances continues to be a national problem. Marijuana is the most widely available and commonly abused illicit drug in the United States. According to the 2013 National Drug Threat Survey (NDTS), 88.2% of responding agencies reported that marijuana availability was high in their jurisdictions.¹ Therefore, the detection of this substance, especially during transportation and storage, is of importance. The current state of the art in concealed contraband detection is the use of a canine. To maintain the operational readiness and reliability of these canines, routine training using training aids must be conducted. Though some law enforcement agencies have been able to satisfy the strict guidelines set forth by the Drug Enforcement Administration (DEA), most agencies are unable to satisfy these requirements and therefore have restricted access to narcotic training aids. This has limited the ability of many canine handlers to perform routine training resulting in shortcomings in a canine team's performance. To alleviate this problem, many canine teams have resorted to the use of odor mimics as a substitute for the use of actual narcotics.

Detector canine teams are trained to detect most commonly found illicit substances. The premise for the detection of illicit narcotic substances is based upon the fact that these substances, though hidden, will emit VOCs. These VOCs are not often the parent drug; they are essentially a chemical associated with the source and provide a reliable indication of the illicit substance. Ongoing research has identified dominant active odor signatures of other major drugs such as cocaine, 3,4-Methylenedioxy-Methamphetamine (MDMA), and methamphetamine, to include methyl benzoate, 3 piperonal, and benzaldehyde, respectively, and effective odor mimics have been created using the identified active odor chemicals.²⁻⁴ Currently, limited information about the volatile components for other popular illicit substances can be found.

The purpose of this study is to identify the odor profile of marijuana for canine detection. For this purpose, headspace analysis of the illicit substance from different batches of marijuana was conducted by Solid-Phase Microextraction-Gas Chromatography/Mass Spectrometry (SPME-GC/MS) for the identification and comparison of similarities and dissimilarities of VOCs present in the each sample. The laboratory's current research has revealed terpene compounds such as caryophyllene, pinene, myrcene, and limonene as common VOCs found in the headspace of the illicit marijuana samples tested. Preliminary canine field tests using isolated samples of these VOCs with certified law enforcement canines have resulted in changes in behavior by canines toward some of these VOCs. Upon completion of this field test, the VOCs that were suspected to produce an alert were combined and again presented to certified canine teams to develop reliable odor mimics for field calibration of detection canines to marijuana. The results of the developed canine odor mimics and their efficacy will be presented as this will result in an overall improvement in seizure rates of these substances by canines.

Illicit Substance, Volatile Organic Compounds, Detector Canines

B61 Using Likelihood Ratios for Source Attribution of Glock® Model 21 Fired Cartridge Cases

Keith B. Morris, PhD, 208 Oglebay Hall, 1600 University Avenue, PO Box 6121, Morgantown, WV 26506-6121; and Catherine L. Hefner, 623 Brownsburg Road, Marlinton, WV 24954*

After attending this presentation, attendees will understand how likelihood ratios are used to interpret impression evidence of pistol cartridge cases.

This presentation will impact the forensic science community by guiding future researchers and firearm examiners to analyze firearm data from the Integrated Ballistic Identification System® (IBIS) (Ultra Electronics Forensic Technology® (UEFT)). Using statistical analysis, the examiner will be able to infer source determinations in a more logical manner.

The purpose of this study was to determine the effectiveness of using likelihood ratios to evaluate the accuracy of source attribution using IBIS® scores. This was achieved by evaluating the error rates of the method when using Bayesian networks to assess the correctness of the attribution using the IBIS® scores for the firing pin and breech face comparisons.

Firearm examiners are prone to criticisms due to the purported lack of consistency when making source determinations.¹ For example, examiners with different educational backgrounds and experiences may draw different conclusions from the examination of the same samples. In particular, vague terminology may contribute to incorrect conclusions of same source attributions. To decrease potential error of terminological inconsistencies, standards should be implemented and universally utilized by firearm examiners.² Additionally, erroneous source determinations may be decreased by eliminating unnecessary, outside information pertaining to the case.³

Researchers commonly use pristine, consecutively manufactured firearms (or parts thereof) to evaluate methodologies. Although this approach reduces variability, pristine conditions may also diminish the generalization of results to real-world conditions.⁴

This research hypothesized that this method will: (1) provide a statistical basis for the interpretation of firearms evidence; and, (2) increase reliability and validity of determining source attributions.

The IBIS® system was used in this research to provide scores of known cartridge cases against a database of both known and unknown cartridge cases. This system measures each case and generates breech face and firing pin scores based on the comparison of a pair of cartridge cases. IBIS® consists of two fully automated comparison systems known as BULLETPROOF®, which compares projectiles, and BRASSCATCHER®, which compares cartridge cases.⁵

This research used a quantitative correlational study design to examine impression evidence on cartridge cases fired by various Glock™ pistols. Twelve Glock™ .45ACP firearms were used for this study. Each gun fired 30 cartridges (reloads: Magtech® Ammunition large pistol primers and Accurate® #2 powder). The firearms were from a local law enforcement agency. Although the firearms are used, the exact number of shots fired through each is unknown.

The firearms were fired at an outdoor shooting range and all cartridge cases were collected from each test fire. The casings were then entered into IBIS® using standard protocols and the candidate matches were organized into Microsoft® Excel®, RStudio® and R® were used to process the data and Netica™ was used to generate a Bayesian network. The Bayesian networks contain the conditional probability tables and density distributions required to interpret new data. Such networks intrinsically incorporate likelihood ratios in the odds form of Bayes' Theorem.

The firing pin score, firing pin rank, breech face score, and breech face rank generated by the IBIS® system were used together with the model, caliber, and firearm identifier of the sample and database firearms to build the network.

B62 Gas Chromatography/Mass Spectrometry (GC/MS) Measurement of Gasoline Vapor Absorption on Clothing in a Confined Space

Sara C. Karp, BS, University of Wisconsin-Platteville, 845 S Chestnut Street, Apt 107W, Platteville, WI 53818; Raymond G. Lenz, BS, Wisconsin State Crime Laboratory-Milwaukee, 1578 S 11th, Milwaukee, WI 53204; Ruth M. Henk, BS, Wisconsin State Crime Laboratory-Milwaukee, 1578 S 11th, Milwaukee, WI 53204; and Charles R. Cornett, PhD*, University of WI Platteville, Dept of Chemistry, Platteville, WI 53818

After attending this presentation, attendees will better understand gasoline vapor absorption on clothing in a confined space.

This presentation will impact the forensic science community by providing experimental data related to the absorption of gasoline vapors by cotton clothing. This has potential ramifications in arson investigations.

A recent case produced a question regarding the possible deposition of gasoline vapors on clothing as a suspect walked across a room in which the vapors were present. In the course of testimony, the defense council noted that gasoline was present on the defendant's footwear, yet there was no determination of gasoline on the defendant's clothing.

Research by Folkman et al., Coulson et al., and Erita et al. (under review) primarily deals with splashing or spilling of ignitable liquids onto clothing and the persistence of sufficient concentrations of ignitable liquids for identification.¹⁻³

The experimental process was as follows. New, never-laundered, same-sourced cotton T-shirts were purchased along with new, one-United States-gallon paint cans. An unventilated, steel flammable cabinet, 1.6m x 0.8m x 0.5m, containing approximately 30L of 87-octane gasoline in standard one-United States-gallon gasoline containers was used as the source of gasoline fumes. Vapors were allowed to accumulate in the cabinet for three months prior to the experiment. Samples were taken in triplicate of cotton T-shirts stored inside the cabinet for six hours, one hour, and 15 minutes. In addition, one experimental condition measured the amount of absorbed gasoline vapor after 15 minutes exposure, followed by a one-hour ventilation in a fume hood. Subsequently, an additional experiment was performed on three T-shirts left hanging one meter from the open doors of the cabinet. Each T-shirt was placed in a clean, new, one-United States-gallon paint can. An activated charcoal strip was suspended in the can which was then heated at 70°C for 16 hours. The activated charcoal strips were washed with carbon disulfide and analyzed by GC/MS.

Results of the experiment show detectable amounts of gasoline (BTEX, alkylbenzenes, and naphthalenes) for the T-shirts exposed to gasoline vapors in the cabinet for periods of six and one hour; however, even in the extremely confined and unventilated space, the T-shirts exposed for 15 minutes did not display sufficient naphthalene concentrations for an identification even prior to the one-hour, in-hood ventilation. The conclusion is that the necessary concentration for gasoline vapors to absorb into cotton T-shirts and be detected would likely lead to the incapacitation or death of the individual wearing the clothing.⁴ The absorption and persistence of solely gasoline vapors onto cotton clothing of a suspect who has left the crime scene appears very unlikely according to the results of these experiments.

Gasoline, Ignitable Liquid, Vapor

B63 Trace Chemical Signatures of Calcium Hypochlorite: Implications for the Attribution of Hypergolic Mixtures

Stephanie A. Yocca, BS, 3940 Oakleys Lane, Richmond, VA 23223; Alicia M. Zimmermann, BS, 1516 Split Oak Lane, Apt C, Henrico, VA 23229; Stephanie R. Harrold, Virginia Commonwealth University, 1015 Floyd Avenue, Richmond, VA 23284; Monique Jones, Virginia Commonwealth University, 1015 Floyd Avenue, Richmond, VA 23284; Joseph B. Ehrhardt, PhD, Virginia Commonwealth University, Dept of Forensic Science, 1015 Floyd Avenue, Rm 2015, Richmond, VA 23284*

After attending this presentation, attendees will understand the basis of chemical variation among sources of inorganic chlorine-based incendiary mixtures and the potential for this variation to support forensic investigations.

This presentation will impact the forensic science community by introducing a new signature system that can determine the source of unknown chemical residues from a crime scene which may be used to establish investigative leads.

Criminal use of self-igniting, or hypergolic, mixtures is a significant issue for law enforcement and forensic laboratories. Many of the possible reactants are available as inexpensive commercial products and chemical ignition of the mixture is easy to execute. As such, hypergolic reactions have been encountered in a range of illicit activities including arson, person-on-person crime, and deployment of improvised explosive devices. One of the more common recipes involves combining inorganic pool chlorine, specifically calcium hypochlorite, with ethylene glycol-based products (e.g., automotive brake fluid). Despite their prevalence, there remain few techniques that can be used to analyze chemical evidence from hypergolic reactions for the purposes of attribution.

The goal of this research was to investigate variation in trace metal composition across different sources of calcium hypochlorite both as precursor compounds and within the post-reaction residues. Metals are likely to differ across sources owing to differences in synthesis routes, trace mineral additives, and levels of purity. Four different types of calcium hypochlorite, three household commercial products, and one laboratory-grade sample were prepared in nitric acid for analysis with Inductively Coupled Plasma/Optical Emission Spectroscopy (ICP/OES). Small-scale reactions with two grams of hypochlorite and one milliliter of polyethylene glycol were made and the residues also analyzed with ICP/OES. Results showed that each hypochlorite source exhibited distinct variation in the presence and relative abundance of certain elements that was consistent in both pre- and post-reaction residues. For example, aluminum was enriched in one sample group (~40ppm) compared to the other sources which were all less than 7ppm while boron was enriched in another sample group (~2ppm) compared to the other sources which were all below the limit of detection. Strontium concentrations were slightly elevated in the laboratory-grade samples versus two High Test Hypochlorite (HTH) commercial brands by 1-2-ppm. Similarly, concentrations of iron were enriched in two sample sources, in comparison to the other commercial source (~8-9ppm vs ~6ppm). Error rates for all measured elements were less than 0.01ppm.

To enhance signature detection and differentiation among reaction residues, ICP/OES data across all 13 elements examined was analyzed with Discriminant Function Analysis (DFA). Results showed robust separation among all three reaction sample groups along the first two functions. Function coefficients revealed that Aluminum (Al), Chromium (Cr), Copper (Cu), Potassium (K), Nickel (Ni), and Strontium (Sr) contributed the most variation among the groups. These may be promising candidates for stand-alone chemical markers for comparing residue samples. Overall, this work suggests that trace metal variation can be used to differentiate each source of calcium hypochlorite and that multivariate metal profiles may be a useful forensic signature for the attribution of hypergolic mixtures involving this type of reactant.

Hypergolic Mixtures, ICP/OES, Trace Metal Signatures

B64 Enantiomeric Identification of Pregabalin Via Methylation and Chiral Derivatization, Utilizing Gas Chromatography/Mass Spectrometry (GC/MS)

Mike Hitchcock, MS, U.S. Postal Inspection Service, Forensic Laboratory Services, 22433 Randolph Drive, Dulles, VA 20104-1000; Ioan Marginean, PhD, George Washington University, 2100 Foxhall Road, NW, Somers Hall L14C, Washington, DC 20007; and Peter Nemes, PhD, George Washington University-Chemistry Dept, 725 21st Street, NW, Corcoran Hall, Rm 107, Washington, DC 20052*

After attending the presentation, attendees will understand the need for a viable method to identify pregabalin, or (S)-3-(aminomethyl)-5-methylhexanoic acid, utilizing traditional capillary GC/MS. Attendees will also be exposed to the methylation and chiral derivatization procedure used to prepare pregabalin for enantiomeric identification by GC/MS. Identification of the correct enantiomer of pregabalin by GC/MS will be demonstrated.

The presentation will impact the forensic science community by demonstrating an alternative method of identifying pregabalin through enantiomeric determination utilizing GC/MS, an instrument commonly found in forensic laboratories.

Many available methods for the identification of pregabalin involve Liquid Chromatographic separation with electrospray ionization Mass Spectrometry (LC/MS). LC/MS is not as common in forensic laboratories as the traditional GC/MS. Alternatively, Fourier Transform Infrared (FTIR) spectrophotometry is an effective way to elucidate the structure of pregabalin; however, FTIR cannot distinguish between optical isomers. Therefore, it would be beneficial to provide a method of enantio-selective identification of pregabalin using GC/MS.

Pregabalin, or (S)-3-(aminomethyl)-5-methylhexanoic acid, marketed under the brand name Lyrica®, became a Schedule V controlled substance in the United States in July of 2005 due to its depressant activity. It is used legitimately to treat neuropathy in diabetic patients as well as for fibromyalgia. Pregabalin is an amino acid and an amphoteric compound, which makes it difficult to analyze using traditional GC/MS instrumentation. Problems associated with GC/MS analysis of pregabalin include: (1) ring closure to the corresponding lactam in the injection port or in the transfer line; as well as, (2) difficulty with chiral derivatization due to lack of reactivity of the derivatization agent in the presence of a carboxylic acid moiety. The ring closure and chiral derivatization problems are overcome by methylating (capping) the carboxylic acid portion of the pregabalin molecule and converting it to its corresponding methyl ester.

The simple procedure used to cap the carboxylic acid portion of pregabalin involves small amounts of thionyl chloride and dry methanol using cold temperatures achieved with dry ice/acetone in a typical laboratory fume hood. Once methylation occurs, the carboxylic acid is deactivated and the attachment of the chiral derivatization reagent (S) Trifluoroacetylpropyl chloride, or (S)-TPC, is straightforward. Once the S-TPC is attached, the correct (S) enantiomer of pregabalin can be identified via GC/MS.

Data will be presented showing the corresponding methyl ester of pregabalin as well as the separation of the (S) and (R) enantiomers via GC/MS. This method will allow for the proper identification of pregabalin utilizing GC/MS, the most common instrumentation found in a forensic drug laboratory.

Pregabalin, Chiral Separation, GC/MS

B65 Analysis of Cannabinoids Found in Seized Marijuana Using Automated Headspace Solid-Phase Microextraction Coupled With Gas Chromatography/Mass Spectrometry

*Jessica Winborn**, 2405B FM 1375, E, Huntsville, TX 77340; *Margaret A. Hanson*, U.S. Customs and Border Protection, LSSD, 4150 Interwood S Parkway, Houston, TX 77032; *Luis E. Figueroa*, U.S. Customs and Border Protection, LSSD, 4150 Interwood S Parkway, Houston, TX 77032; *Ashley R. Konarik*, MS, PO Box 524, East Bernard, TX 77435; *Dustin M. James*, MBA, U.S. Customs and Border Protection, LSSD, 4150 Interwood S Parkway, Houston, TX 77032; *Kevin K. Chen*, BS, U.S. Customs and Border Protection, LSSD, 4150 Interwood S Parkway, Houston, TX 77032; *Terra M. Dassau*, PhD, U.S. Customs and Border Protection, LSSD, 4150 Interwood S Parkway, Houston, TX 77032; *James D. Sweet*, PhD, U.S. Customs and Border Protection, LSSD, 4150 Interwood S Parkway, Houston, TX 77032; and *Jorn Chi-Chung Yu*, PhD, Sam Houston State University, Dept of Forensic Science, Box 2525, Huntsville, TX 77341

After attending this presentation, attendees will better understand automatic headspace solid-phase microextraction methodology and its application to the analysis of *Cannabis sativa* L. plant material.

This presentation will impact the forensic science community by providing an automated method for the direct headspace sampling of cannabinoids from solid samples of suspected marijuana. This presentation will enhance the applicability of Headspace Solid/Phase Microextraction coupled with Gas Chromatography/Mass Spectrometry (HS/SPME/GC/MS) to controlled substance analysis.

After attending this presentation, attendees will gain an understanding of the use of HS-SPME methodology to identify and quantify cannabinoids in marijuana samples.

The term marijuana refers to the plant material of *Cannabis sativa* L. There are more than 60 natural cannabinoids found in marijuana. The primary psychoactive component is Δ^9 -tetrahydrocannabinol (Δ^9 -THC). Current analytical methods for the detection of cannabinoids and other natural constituents of marijuana include solvent extractions followed by gas or liquid chromatography. Such methods have several limitations, including the use of hazardous solvents, the expense of said solvents, disposal of the waste generated from solvent use, and the time needed to perform such extractions. A solution that may eliminate such limitations for the detection of cannabinoids in marijuana samples is the use of HS/SPME/GC/MS.

In this research, an optimal automated HS/SPME/GC/MS method has been developed using cannabinoid standard reference materials and actual marijuana material samples. Internal standards and any standard reference samples used were placed in a vial and the solvent evaporated before analysis. The plant material was ground and sieved before being weighed out into sample vials. Unlike previous methods that would require the sample to be extracted with solvents before analysis, the HS/SPME/GC/MS method required the sample to be sealed in the sample vial and placed on a GC/MS autosampler that would carry out the HS/SPME extraction using a Polydimethylsiloxane (PDMS) 23-gauge, 100 μ m absorbent fiber and inject the extracted sample into the GC/MS. The optimized extraction temperature for cannabinoids was found to be 150°C and the optimal extraction time was found to be five minutes. Regeneration of the PDMS fiber was achieved by heating the fiber to 250°C in the autosampler conditioning chamber during the run after the fiber was exposed to the inlet of the GC/MS.

Results from the optimized HS/SPME/GC/MS method show the method to be comparable to the common liquid extraction method. The same cannabinoids can be seen with both methods and in some cases the HS/SPME/GC/MS method shows more cannabinoids than the liquid extraction suggesting it has a higher sensitivity. Chemical constituents of marijuana other than cannabinoids could also be extracted and detected with the optimal HS/SPME/GC/MS method. Future research will include statistical analysis of the data collected from marijuana plant samples using this method with the goal being to determine whether or not two samples share a common origin.

Marijuana, HS Solid-Phase Microextraction, Drug Analysis

B66 Identifying Emerging Drugs of Abuse

Elizabeth A. Gardner, PhD, UAB Department of Justice, UBOB 210, 1530 3rd Avenue, S, Birmingham, AL 35294-4562*

After attending this presentation, attendees will understand the process of identifying emerging drugs of abuse discovered through internet searches of drug forums and vendors of legal highs. This will include: (1) the misinformation offered by vendors of legal highs; (2) how to identify potential structural isomers and diastereomers; (3) using Nuclear Magnetic Resonance (NMR) to distinguish between isomers with similar mass spectra but different retention Gas Chromatographic (GC) retention times; and, (4) combo drugs.

This presentation will impact the forensic science community by raising awareness about identifying emerging drugs of abuse, identifying misinformation offered by the vendors, and discussing issues to be considered in developing a method for analytical analysis.

Legal highs are analogs of controlled substances that retain the psychoactive and addictive properties of the parent drug. The most recent influx of legal highs has been cannabimimetics and cathinones marketed as “Spice” and “bath salts,” respectively. They can be purchased in gas stations, head shops, or online, often by minors. As the components in the different “Spice” and “bath salts” products have been scheduled, new analogs have been introduced to take their place. Their manufacture is not regulated and best practices cannot be ensured. Because legal highs are not developed as potential pharmaceuticals, there is little or no clinical data available so emergency medical personnel have no guidelines for treatment in the case of overdose.

The focus will be on three new legal highs: (2-aminopropyl)-benzofuran (APB), methiopropamine (MPA), and 4-methyl pentedrone (4-MPD), each purchased from online vendors of research chemicals. There are four potential positional isomers of APB, 4-, 5-, 6-, and 7-APB. Both 5- and 6-APB are offered for purchase as legal highs. The isomers have distinct GC retention times that are confirmed by NMR. Analysis shows that both the 5- and 6-APB are being provided as claimed.

Methiopropamine is a thiophene analog of methamphetamine. It is often offered as part of a combo-drug, where two mildly psychoactive drugs are combined in an effort to mimic a controlled substance. Two samples of M&M were analyzed and contained MPA and 5,6-Methylenedioxy-2-Aminoindane (MDAI) as advertised. A sample of synthacaine, purported to be a mixture of MPA and dimethocaine, was actually a mixture of MPA and benzocaine.

Finally, the analysis of a product labeled 4-MPD is offered as an example of a legal high where the name and structure posted on the vendor’s web page did not match the drug. According to the name, it is pentedrone with a methyl group attached at the para position on the benzene ring. The structure that was posted on several vendor web pages was 2-(methylamino)-1-phenylbutan-1-one (buphedrone). When analyzed, the substance was actually 2-(ethylamino)-1-(4-methylphenyl)pentan-1-one (MEAP).

Legal High, Drug Analysis, Analog

B67 The Development of New Enzymes for 20-Minute Rapid Direct Amplification of Crime Scene Samples and Its Application in Presumptive DNA Screening

*Steven B. Lee, PhD**, San Jose State University, 1 Washington Square, Macquarrie Hall 521, San Jose, CA 95192; *George T. Duncan, PhD*, Broward County Crime Lab, 201 SE 6th Street, Rm 1799, Fort Lauderdale, FL 33301; and *Bruce R. McCord, PhD*, Florida International University, Dept of Chemistry, University Park, Miami, FL 33199

After attending this presentation, attendees will understand how new inhibitor-resistant, rapid polymerases may be used to type blood, saliva, and semen.

This presentation will impact the forensic science community by showing how ultimately the development of direct, rapid Polymerase Chain Reaction (PCR) -based systems will greatly expand the capabilities of police, custom agents, and first responders to process crime scene samples and mass disasters, providing information on a timely basis that otherwise might take hours to obtain. Because these procedures involve existing commercial systems, issues such as injection, loading, and reliability have already been worked out through extensive marketplace testing. The analytical systems have very small footprints and the chips and PCR tubes are disposable and easy to transport. These systems can be implemented immediately and incorporated into current forensic labs with only the addition of a fast thermal cycler and no complex training or engineering design. The overall result will be a massive improvement in the current processing of submitted DNA samples and in the capability to perform remote testing and screening.

Current DNA typing methods provide the best biometric information yielding potential identity, kinship, and geographical origin, but they are not sufficiently fast to permit rapid identity of a suspect. There are situations in which it is very important to rapidly screen crime scene samples and unknown individuals who may have been involved in a crime. Examples include seized evidence potentially linked to a suspect, commingled bone samples buried in a mass grave, or the determination of which bloodstains present at a crime scene may be probative. In these situations, many samples may need to be run in order to create probable cause for detaining a suspect. The goal of this project is to develop a rapid and direct method for determining DNA from a wide variety of crime scene samples. Rape kit screening will also be possible.

In the first phase of this study, a rapid thermal cycling procedure combined with a direct amplification was tested and optimized on control DNA standards, K562, 9948, and 9947a cell lines, and paper saliva punch samples from 20 individuals. Optimization included testing different polymerases, buffer compositions, salt concentration, pH, and varying concentrations of magnesium and dNTPs, as well as thermal cycling parameters. It was demonstrated that the rapid direct PCR using rapid DNA polymerases (Z-Taq™ Polymerase) and direct PCR buffer (AnyDirect™ F buffer with 30 cycles at 98°C for five seconds, 60°C for ten seconds, and 72°C for 15 seconds) permitted a high-speed amplification of a 7-locus multiplex that required no extraction step. A 1.2mm punch of samples from FTA® paper was directly added to the rapid direct master mix and amplification performed in 15 minutes and 54 seconds on rapid thermal cyclers. This was then coupled with a short 1.8cm microfluidic electrophoresis system and it was shown that the entire procedure from paper punch to genotype can be completed in under 25 minutes.

In the second phase of this study, mutant taq polymerases that are inhibitor resistant were tested on replicate samples spiked with hematin or phenol chloroform. Different volumes of the OmniTaq™ polymerases were tested on control DNA with varying amounts of inhibitors. The new enzymes were capable of partially overcoming the inhibition induced by hematin (15µM) and phenol chloroform (0.4µl).

In the third phase of this project, the proven high-speed thermal cyclers and rapid enzymes capable of performing 28 cycles of amplification in 14 minutes or less, in combination with the new inhibitor resistant enzymes on different biological fluids, will be tested. This procedure will be coupled with high-speed genotyping using microfluidic chips or standard capillary-based systems modified for faster run times.

Rapid direct PCR procedures can greatly speed the processing time but they primarily work with saliva.^{1,2} The goal is to perform high-speed DNA detection for a wider variety of sample types including blood, bone, and sexual assault kits. Specially engineered enzymes will be used, high-speed thermal cyclers, and chip-based electrophoresis, as well as inhibitor-resistant DNA polymerases to achieve sample genotypes in less than 20 minutes for a wide variety of sample types.³⁻⁵ The goal will be to provide methods for any crime laboratory to obtain genotypes in less than 40 minutes using off-the-shelf, high-speed thermal cyclers and novel polymerases and in less than 20 minutes using a commercial microchip prototype.¹

This project is interdisciplinary involving the efforts of instrument manufacturers, biochemistry research, and law enforcement.

Rapid, Direct PCR, Inhibition, DNA Polymerase

B68 Examination of Factors That Affect the Recovery and Analysis of DNA From Spent Cartridge Casings

Rebecca Ray, BS, Michigan State University, 560 Baker Hall, East Lansing, MI 48824; Ashley M. Mottar, MS, 560 Baker Hall, East Lansing, MI 48824; and David R. Foran, PhD, Michigan State University, Forensic Science Program, 560 Baker Hall, East Lansing, MI 48824*

After attending this presentation, attendees will understand the effects a number of variables, including pre-processing for fingerprints, DNA isolation methods, and cartridge size, have on the retrieval and analysis of DNA from spent cartridge casings.

This presentation will impact the forensic science community by providing instruction on which DNA retrieval methods and other variables have the greatest influence on recovering and analyzing DNA from spent cartridge casings. The findings have the potential to influence methods used by practitioners and will aid in prioritizing samples based on the likelihood of recovering genetic information on the loader of a firearm.

Hundreds of thousands of crimes involving firearms are committed annually in the United States; therefore, it is extremely important to identify the person who fired a weapon.¹ The weapon itself is rarely found at a crime scene; however, spent cartridge casings are, which could potentially link the shooter to both the firearm and the crime. Some forensic laboratories have attempted to isolate and analyze DNA from spent cartridge casings, though this has met with little success. Recent research in this study's laboratory has shown that optimized DNA extraction methods can improve the number of Short Tandem Repeat (STR) alleles generated from spent casings, yet there are many other factors that have the potential to influence the recovery of genetic information, several of which were examined in this research.

The effect of cyanoacrylate fuming was studied by having volunteers load nine cartridges into the magazine of a firearm at the Michigan State Police Lansing Laboratory, firing the cartridges, and collecting the casings. One-third of the spent casings were fumed with cyanoacrylate on site, one-third were transported to the Michigan State University laboratory and fumed, and the remaining third were not fumed. DNA was recovered using a double-swab method, utilizing one wet and one dry swab, followed by an organic extraction procedure previously optimized in the laboratory. DNA yields were determined using an Alu-based real-time Polymerase Chain Reaction (PCR) assay, and STRs were analyzed using the Promega® PowerPlex® Fusion Kit. The number of alleles consistent with the handler (established via a buccal swab) and the percent profile recovered were calculated. Statistical differences among methods were determined using the Mann-Whitney test at a significance level of 0.05.

Swabbing strategies and the influence of cartridge size were also examined simultaneously. Volunteers loaded twelve rounds each of 0.22 and 0.45 caliber cartridges into magazines, the cartridges were fired, and the casings collected. Three of the casings were swabbed individually, while the remaining casings were cumulatively swabbed in sets of three. DNA was extracted, quantified, and STR profiles were produced as above.

Cyanoacrylate fuming had a negative effect on DNA yields, as non-fumed casings had a significantly higher DNA yield than fumed casings. This was confirmed by STR results, wherein non-fumed casings generated an average of 27 loader alleles, while casings fumed both on-site and in the laboratory produced a third as many. Cumulative swabbing recovered an average of 2.6pg/μL of DNA from the 0.45 caliber casings, which was significantly higher than the average 0.9pg/μL recovered through individual swabbing, thus allowing for more DNA to be added to PCR reactions. As a result, cumulative swabbing recovered a higher percentage of the loader's profile, averaging 25 loader alleles compared to 14 recovered through individual swabbing. Similarly, an average of 0.75pg/μL and 12 alleles were recovered from cumulatively swabbed 0.22 casings, while 0.4pg/μL and 6 alleles were recovered from individually swabbed casings. Regardless of swabbing strategy, 0.45 casings produced more DNA and more STR alleles than did 0.22 casings. Overall, each tested variable was found to have a substantial effect on DNA yields and STR profiles, and therefore needs to be strongly considered when DNA analysis from spent casings is undertaken.

A portion of this project was supported by grant number 2013-DN-BX-K039, awarded by the National Institute of Justice, Office of Justice Programs, United States Department of Justice. Points of view in this document are those of the authors and do not necessarily represent the official position or policies of the United States Department of Justice.

DNA Recovery from Casings, Cartridge Casings, Touch DNA

B69 Maximizing DNA Recovery and Short Tandem Repeat (STR) Data From Spent Cartridge Casings

Ashley M. Mottar, MS, 560 Baker Hall, East Lansing, MI 48824; and David R. Foran, PhD, Michigan State University, Forensic Science Program, 560 Baker Hall, East Lansing, MI 48824*

After attending this presentation, attendees will understand the highly improved performance of optimized methods for touch DNA recovery and analysis from spent cartridge casings, which are commonly retrieved from shooting incidents.

This presentation will impact the forensic science community by providing improved procedures for recovering and amplifying DNA from spent cartridge casings in order to increase DNA yields and STR data. The findings have the potential to influence the techniques scientists utilize when analyzing DNA from spent casings, ultimately connecting an individual to a crime based on the presence of their genetic material on casing evidence.

Firearms, particularly pistols, are commonly used in violent crimes, though the weapon is rarely recovered. Nevertheless, spent cartridge casings ejected during firing are often recovered by law enforcement and may contain DNA deposited by the loader of the firearm, who could potentially be identified via STR analysis. DNA recovered from spent casings; however, is often degraded and present in low copy numbers. Owing to this, crime laboratories have had limited STR typing success from casings; thus, it is essential that effective methods for DNA recovery and analysis are determined.

Previous research in this study's laboratory examined multiple variables in cell/DNA isolation to improve DNA yields and typing results from spent casings, including swabbing versus soaking casings, the duration of digestion, shaking during digestion, etc. Based on the results, in the current study, DNA yields were examined and STR profiles were generated using five optimized methods: swabbing or soaking with an organic extraction, swabbing or soaking with a silica-based extraction (QIAamp® DNA Investigator Kit), or swabbing with a non-binding DNA extraction (Fingerprint DNA Finder® Kit). Volunteers loaded uncleaned cartridges into the magazine of a pistol, the cartridges were fired, and the casings were collected. The first method consisted of swabbing casings with a wetted swab followed by a dry swab. The second method involved fully submerging casings in digestion buffer for 30 minutes, transferring the buffer to microcentrifuge tubes, then swabbing the casings with a dry swab, and incubating the tubes containing the soaking solution and swabs at 85°C for ten minutes. Proteinase K was added to all samples, which were digested for one hour with concurrent shaking at 900rpm. Organic or QIAamp® extractions were then conducted, with the former followed by purification using an Amicon® column pre-treated with yeast RNA. FDF® processing followed the manufacturer's instructions. DNAs were quantified and amplified with AmpFISTR® MiniFiler™ and/or PowerPlex® Fusion kits. Statistical analysis of DNA yields, the percent of loaders' STR profiles recovered, and allelic consistency with the loader were performed.

Significantly more loader alleles were amplified using Fusion than MiniFiler™, while the average number of non-loader alleles did not differ. Therefore, Fusion was used for subsequent analyses. Overall, organic extractions of swabbings or soakings yielded significantly more DNA than QIAamp® or FDF®. Further, double swabbing and organic extraction resulted in significantly higher DNA yields than the other four methods and generated, on average, 30% of loaders' profiles (~12 alleles), including some full 24 locus profiles. Organic extraction of soaked samples produced the second-highest amount of DNA, and an average of 10 loader alleles. QIAamp® purification of swabbed or soaked samples recovered significantly less DNA and resulted in fewer STR alleles than those organically extracted. The non-binding DNA extraction, which was specifically designed for touch samples, generated minimal or no loader alleles (an average of only 2.7% loaders' profiles); however, the method that produced the most DNA (double swabbing and organic extraction) also resulted in the most non-loader/drop-in alleles, although their prevalence was concentrated in a small percentage of samples and were generally of undeterminable origin. Taken together, these findings indicate that genetic analysis can become a viable tool for identifying the loader of a firearm, increasing the probative value of this type of evidence.

Cartridge Casings, DNA From Touched Objects, STR Analysis

B70 Internal Validation and Comparative Analysis of the Promega® PowerPlex® Fusion and the Applied Biosystems® GlobalFiler™ Express Amplification Kits for Direct Amplification

Betzaida L. Maldonado, BS, 1357 Park Street, Apt 3, Huntington, WV 25701; Jessica Skillman, BS, DC Department of Forensic Sciences, 401 E Street, SW, 3rd Fl, Washington, DC 20024; Jennifer L. Zeffer, MS, 401 E Street, SW, Washington, DC 20024; Laura Kuyper, MSFS, Marshall University Forensic Science Center, 1401 Forensic Science Drive, Huntington, WV 25701; and Pamela J. Staton, PhD, Marshall University Forensic Science MSFS & Center, 1401 Forensic Science Drive, Huntington, WV 25701*

After attending this presentation, attendees will better understand the key differences between the Promega® PowerPlex® Fusion and the Applied Biosystems® GlobalFiler™ Express Amplification Kits based on comparison and internal validation studies completed at the Department of Forensic Sciences. The evaluation focuses on the ability to amplify blood and saliva samples from FTA cards, as well as buccal swabs, in the same 96-well plate using a single cycle number and one optimal injection time.

This presentation will impact the forensic science community by explaining how the internal validation and comparison of Promega® PowerPlex® Fusion and the Applied Biosystems® GlobalFiler™ Express Amplification Kits will educate attendees on the performance of both Polymerase Chain Reaction (PCR) amplification kits. This comparison highlights the key differences in the kit protocols and overall results. The optimization of three different types of reference samples into a single cycle number and one optimal injection time will assist the laboratory with manual sample throughput until a fully automated workflow can be established.

In 2010, the Federal Bureau of Investigation (FBI) Combined DNA Index System (CODIS) Core Loci Working Group identified reasons for expanding the CODIS Core Loci in the United States. Among the reasons is a need to increase international data compatibility and the power of discrimination in missing person cases.

Both the Promega® PowerPlex® Fusion and the Applied Biosystems® GlobalFiler™ Express PCR systems have adapted to the extension of the CODIS Core Loci by increasing their multiplex reactions to 24 loci. The PowerPlex® Fusion Amplification Kit is a five-dye system that allows for the amplification and fluorescent detection of the 13 core CODIS (United States) loci and the 12 core European Standard Set loci. The GlobalFiler™ Express Amplification Kit is a six-dye assay that targets 21 autosomal STR loci, one Y-STR locus, and one Y insertion/deletion locus. Both the PowerPlex® Fusion and the GlobalFiler™ Express Amplification Kits have been approved for the National DNA Index System (NDIS). Therefore, the evaluation of both kits is important in determining the best fit for each individual laboratory as these are implemented for DNA testing.

Sensitivity, precision, concordance, reproducibility, and contamination studies were completed as part of the internal validation of the PowerPlex® Fusion and the GlobalFiler™ Express Amplification Kits using the Applied Biosystems® 3500 Genetic Analyzer. In addition, sample preparation, injection time, analytical threshold, and stochastic threshold were determined to optimize the protocol for analysis of blood and saliva on FTA® cards and buccal samples. The goal of the validation was not only to ensure that both kits produced reliable and robust results, but to also optimize a single thermal cycling parameter and one optimal injection time for all three types of samples.

The internal validation determined that for the PowerPlex® Fusion Amplification Kit, optimal results for blood and saliva on FTA® cards, as well as buccal samples, can be obtained with 26 amplification cycles and 12 second injections on the Applied Biosystems® 3500 Genetic Analyzer. Alternatively, for the GlobalFiler™ Express Amplification Kit, optimal results for these three types of samples can be obtained using 25 amplification cycles and 15 second injections on the Applied Biosystems® 3500 Genetic Analyzer. The ability to amplify and inject blood and saliva from FTA® cards and buccal reference samples on the same 96-well reaction plate will assist the laboratory with manual sample throughput until a fully automated workflow can be established.

GlobalFiler™ Express, PowerPlex® Fusion, Direct Amplification

B71 High-Throughput Spermatozoa Detection Using the Proximity Ligation Real-Time PCR (PLiRT-PCR) Method

Chin Hong Shek, BSc, 1400 S Joyce Street, Apt 518, Arlington, VA 22202; Valerie Clermont Beaudoin, BS, 1930 37th Street, NW, Washington, DC 20007; Jaclyn Benjamin, BS, 1401 S Joyce Street, Apt 305, Arlington, VA 22202; and Daniele S. Podini, PhD, Department of Forensic Science, 2100 Foxhall Road, NW, Washington, DC 20007*

After attending this presentation, attendees will be informed of how the PLiRT-PCR method has been improved for high throughput spermatozoa detection in forensic applications.

This presentation will impact the forensic science community by demonstrating that the PLiRT-PCR method can confirm the presence of spermatozoa from large quantities of samples simultaneously in a streamlined process, demonstrating potential to replace the time-intensive microscopic detection method currently in use.

In the processing of sexual assault evidence, mass media often places emphasis on obtaining a suspect DNA profile; however, equally important but rarely acknowledged is the need for confirmatory identification of spermatozoa, which is often a critical step in determining whether a sexual act occurred or not.

Currently, the only universally accepted method to confirm the presence of spermatozoa is to visualize it microscopically; however, the method has low efficiency as each sample has to be examined individually. Automated fluorescence-based microscopic detection can decrease the time spent per sample, but still processes one sample at a time and requires expensive equipment. Therefore, an alternate method that is capable of processing multiple samples at a time with high accuracy would be a strong candidate for replacing the microscopic method.

The PLiRT-PCR assay combines the specificity of an immunological reaction with the sensitivity of PCR to detect sperm-specific proteins in samples. Specific antibody probes bind simultaneously to target proteins to achieve proximity ligation of conjugated oligonucleotides and the resulting DNA product is detected via real-time PCR. The amount of signal corresponds to the amount of ligated product, which in turn indicates the amount of protein in the sample. The assay only requires a real-time PCR instrument, which is commonly used in forensic laboratories.

The assay has been tested using antibodies targeting two sperm-specific proteins, SP-10 and CRISP-2. Both targets were selected for their localization inside the acrosome of the spermatozoa, which protects them from environmental damage until lysis, increasing the chance of successful detection even with aged samples.

Previously, the assay reported high variability between reactions running aliquots from the same sample. This not only affected the reproducibility of results but also significantly diminished the sensitivity of the assay, as the threshold value for spermatozoa detection is based on three times the standard deviation of Cycle threshold (Ct) values from a set of five No Protein Controls (NPCs). Through protocol and reagent optimization, variability issues have been reduced significantly, with NPCs standard deviations often reaching as low as 0.5 Ct. Testing of both antibodies after optimization places their limit of detection at a 1:100 semen dilution for SP-10 and a 1:1000 semen dilution for CRISP-2, which are conservatively equivalent to 600 and 60 spermatozoa in the assay, respectively. High throughput experiments were also carried out with the Applied Biosystems® 7500 Real-Time PCR System using samples eluted from cotton swabs to simulate actual forensic evidence. In this set-up, three semen swab sample eluates from 2012, 2013, and 2014, as well as a positive control of a 1:100 semen dilution, were run in duplicate along with a set of eight NPCs, in which semen swabs prepared in 2012 and 2014 were successfully detected by the assay.

While these results show promise, several issues have been found. For instance, the probe development process requires further improvement, particularly in the antibody biotinylation step. Also, the new SP-10 antibodies exhibited much less sensitivity than before (reported to be at a 1:5000 semen dilution), whereas CRISP-2 antibodies were found to cross-react with CRISP-3, a protein expressed in salivary glands. As assay development continues, other antibodies that target similar semen-specific proteins will be tested in search of one that provides good balance between sensitivity and specificity. This presentation will discuss the experiments conducted using the optimized PLiRT-PCR protocol, covering the setup, procedure, and results from high throughput runs. The difficulties and potential for further development will also be discussed.

Spermatozoa, Proximity, Ligation

B72 Developing a Dynamic Model of the DNA Laboratory Process to Characterize the Sources of Uncertainty in DNA Signal: Applications to Forensic DNA Education, Training, and Validation

Genevieve Wellner, MS, Boston University, School of Medicine, Program in Biomedical Forensic Sciences, 72 E Concord Street, Rm R806, Boston, MA 02118; Kayleigh Rowan, MS, Colorado Bureau of Investigation, 2797 Justice Drive, Grand Junction, CO 81506; Cheng-Tsung Hu, BS, 72 E Concord Street, Rm R806, Boston, MA 02118; and Catherine M. Grgicak, PhD, Boston University, School of Medicine, Biomedical Forensic Sciences, 72 E Concord Street, Rm R806D, Boston, MA 02118*

After attending this presentation, attendees will understand the ways in which the DNA laboratory process can be dynamically modeled using a systems-thinking approach. Attendees will also be made aware of how the model can be modified by the user in order to test the impacts of various systems and their errors.

This presentation will impact the forensic science community by demonstrating that a dynamic model can be utilized to train students and practitioners in the nuances associated with the forensic laboratory process. This presentation will demonstrate that modifying the Polymerase Chain Reaction (PCR) efficiency and the error in PCR can substantially impact the peak heights and peak height ratios. Further, it will be demonstrated that dilution of a concentrated stock solution during validation results in additional peak height variability and may need to be considered a process which introduces additional stochastic effects not typically introduced during evidence processing.

The model mimics the generation of a random 16-locus profile obtained by following these steps: extraction→quantification→dilution→amplification→electrophoresis. The input values that can be modified by the user are shown in the Table below.

	Unit	Range	Description
Nominal Target based on qPCR	ng	0-10,000	The target value obtained in the DNA extract as per qPCR.
% RSD in qPCR	%	0-100	Relative standard deviation associated with qPCR results.
Buffer 1 switch	μL	0-1,000	Volume of buffer utilized when the DNA extract is diluted.
Buffer Pipette 1 Stdev	μL	0-10	Standard deviation of the pipette volume during the first dilution.
Buffer 2 switch	μL	0-1,000	Volume of buffer utilized when the DNA is serially diluted twice.
Buffer Pipette 2 Stdev	μL	0-10	Standard deviation of the pipette volume utilized during the second serial dilution.
Buffer 3 switch	μL	0-1,000	Volume of buffer utilized when the DNA extract is serially diluted three times.
Buffer Pipette 3 Stdev	μL	0-10	Standard deviation of the pipette volume utilized during the third serial dilution.
Number of PCR Cycles		28-29	The number of PCR cycles.
Deviation in PCR Efficiency		0-0.2	The PCR efficiency is different at each cycle and is normally distributed about 1. It is the standard deviation of the PCR efficiency. It is set such that the efficiency decreases from 1 as the number of amplicons increase, as per $1 - e^{-(4.5 \times 10^{-10} \cdot [DNA]^c)}$, where c is the cycle number.
Stutter Ratio Information		0-1	Mean and standard deviation of the stutter ratios for each locus.
Cumulative Population Statistics		0-1	Cumulative allele frequencies for 15 STR loci.
CE Sensitivity	RFU		The increase in average RFU signal with amplicon. It can be approximated by determining the slope of a the linear portion of a graph which plots the average peak signal ($\frac{RFU}{RFU}$) for heterozygous loci versus $2C_{tot}[DNA]_0$, where C_{tot} is the total number of cycles (i.e., 28 or 29) and $[DNA]_0$ is the template mass.
RSD of CE		0-1	Relative standard deviation of the capillary electrophoresis set-up and injection.

Criminalistics Section - 2015

The dynamic model treats each copy of DNA as an independent molecule (i.e., no molecular interaction) without systematic preference for one allele over another. The number of copies varies as per the Poisson distribution for each aliquot. For example, if there is an average of 16 copies of DNA in an aliquot, the aliquot that is actually taken may contain 15 copies of allele 1 and 16 of allele 2. The PCR efficiency is different for each allele amplified and varies at each cycle. Thus, the PCR efficiency of cycle 27 may be 0.976 for one allele and 0.983 for another allele. During cycle 28 the PCR efficiency may be 0.979 and 0.980 for allele 1 and 2, respectively. Stutter ratios and CE sensitivity are treated similarly.

The output of the dynamic models gives the user information on: (1) the actual number of alleles/molecules added to the PCR; (2) the known genotypes; and, (3) the electropherogram.

Testing shows that decreasing the deviation in PCR efficiency decreases the differences in peak heights between alleles. Further, it has been determined that peak height differences increase when samples are serially diluted.

DNA Laboratory Validation, System Thinking, Dynamic Model DNA Laboratory

B73 Room Temperature DNA Preservation and Rapid Purification of Decomposing Human Tissue Samples: An Alternative DVI Approach

*Amy E. Sorensen**, 11 Webb Creek Place, The Woodlands, TX 77382; *Elizabeth Rahman, BS*, 14422 Cypress Leaf, Cypress, TX 77429; *Cassandra Canela, BS*, 3218 Hamm Road, Pearland, TX 77581; *James L. White, BS*, 9720 Broadway Street, Apt 523, Pearland, TX 77584; *David A. Gangitano, PhD*, 13906 Paradise Valley Drive, Houston, TX 77069; and *Sheree R. Hughes-Stamm, PhD*, Sam Houston State University, Dept of Forensic Science, Huntsville, TX 77341

After attending this presentation, attendees will be provided with information regarding the efficiency of various solutions to preserve DNA in decomposing skin and muscle samples when stored in tropical ambient temperatures for up to three months. In addition to the benefits of storing samples at room temperature, this presentation will also describe the results of combining these preservatives with various purification methods in order to more rapidly process a high volume of tissue samples for DNA identification.

This presentation will impact the forensic science community by examining how these technologies may have an important impact in the field of forensic genetics and for Disaster Victim Identification (DVI) protocols regarding DNA identification in particular. The application of enhanced liquid tissue preservatives coupled with a reduced DNA extraction procedure may improve the sample processing throughput during a mass fatality incident. Therefore, the implementation of these techniques in future mass disaster responses may help preserve the quality of DNA and improve Short Tandem Repeat (STR) results from decomposing human tissues by improving sample preservation methods and providing a more direct and streamlined high-throughput strategy for processing those samples.

After a mass fatality incident, adequate freezer facilities to house victims may not be available and, therefore, rapid decomposition of bodies will be seen in hostile climates. In order to minimize the DNA degradation, and maximize throughput of samples for identification, an ideal preservative would protect the DNA within tissues while also leaching DNA into the surrounding solution. By maximizing the quantity and quality of “free” DNA in the preservative solution, the time-consuming steps of tissue digestion and DNA extraction may be eliminated.

Skin and muscle samples were harvested over a two-week time period in early fall from three human cadavers placed in an open field at the Southeast Texas Applied Forensic Science facility in Huntsville, TX. Five liquid preservatives (LST, DESS, modified TENT, DNAgard® Tissue, and RNAlater®) were evaluated at 35°C and 60% to 70% humidity for up to three months of storage. DNA was extracted from tissues using the QIAamp® DNA Investigator kit on the QIAcube® platform. The efficiency of isolating the “free” DNA directly from the liquid preservative was tested using the QIAamp® DNA Investigator kit, QIAquick® PCR purification kit, modified ethanol precipitation followed by Microcon® filtration, Agencourt® AMPure® XP PCR Purification system, and the Fingerprint DNA Finder (FDF) kit.

All solutions except the LST buffer adequately preserved the DNA in fresh and decomposed skin and muscle. RNAlater® consistently generated the highest DNA yields (up to 250ng/μL); however, DNAgard® and the modified TENT buffer were the only two preservatives which consistently leached high amounts (0.06-40ng/μL) of good quality DNA into solution for DNA isolation and successful genotyping using the AmpFISTR® IdentiFiler® Plus STR Amplification kit.

The QIAquick® PCR purification kit was the best method tested. It isolated adequate amounts of DNA (0.5-4ng/μL) from all tissues to produce complete profiles in less than 25 minutes. Results suggest that DNAgard® and the modified TENT buffer are better at leaching and simultaneously protecting the “free” DNA in solution than the other methods tested. Therefore, extracting DNA directly from the DNAgard® or the modified TENT buffer preservative using the QIAquick® purification kit may be the best options for room-temperature storage and rapid sample processing in cases of mass disasters.

DNA Preservation, DNA Extraction, DVI

B74 Further Development of an Short Tandem Repeat (STR) Multiplex Reaction for Teaching and Research Purposes

*Charmaine L. Williams, BS**, SUNY-University at Albany, 1400 Washington Avenue, Albany, NY 12222; *Sarah A. Lusk, MSFS*, University of Alabama at Birmingham, UBOB 210, 1720 2nd Avenue, S, Birmingham, AL 35294; and *Jason G. Linville, PhD**, University of Alabama at Birmingham, UBOB 210, 1720 2nd Avenue, S, Birmingham, AL 35294-4562

After attending this presentation, attendees will be familiar with a Short Tandem Repeat (STR) multiplex reaction which is cost-effective for educational and research purposes and will understand how multiple variables affect the validation of novel STR kits.

This presentation will impact the forensic science community by allowing more students to gain hands-on experience with affordable STR amplification reactions while reducing the cost of performing multiplex reactions for academic research programs.

The commercial STR multiplex kits utilized in forensic DNA laboratories are capable of amplifying the 13 core STR loci, amelogenin, and additional loci to provide high discriminatory power when identifying an individual. Producing a rare genotype specific to an individual may not be necessary when STR multiplex reactions are used for teaching in forensic biology laboratory courses. Amplification of fewer loci may also be sufficient for analysis of research samples. Developing a reliable multiplex amplification reaction that costs less than reactions using current commercial kits would be useful to teaching and research labs.

Previous work at the University of Alabama at Birmingham developed a multiplex reaction capable of amplifying three loci: D3S1358, TH01, and vWA.¹ Split peaks for vWA alleles made the interpretation of data difficult, so a new reaction was developed replacing vWA with D13S317. This presentation focuses on the development of a ladder and a sensitivity study for a multiplex reaction using D3S1358, TH01, and D13S317 loci.

An allelic ladder was prepared from amplified volunteer DNA. Chelex extractions of buccal swabs from 13 volunteers were quantitated before amplification. A primer mix of fluorescently labeled primers for D3S1358, TH01, and D13S317 was prepared and combined with a commercial Polymerase Chain Reaction (PCR) amplification mix for all amplifications. Amplified product was separated and analyzed using an Applied Biosystem® 310 Genetic Analyzer and Genemapper® ID software. The peak heights among the three loci were not balanced in initial electropherograms. This imbalance was corrected by adding additional TH01 primers to the prepared primer mix and re-amplifying samples. Amplified product from ten selected samples was combined to form a working allelic ladder for the multiplex reaction. New panel and bin text files were created based on the alleles present in the allelic ladder.

A sensitivity study was performed using the D3S1358, TH01, and D13S317 multiplex reaction. A set of serial dilutions was prepared from two volunteer samples and one control DNA sample. Each sample was amplified in triplicate using the primer mix and PCR amplification mix described above, with either 10ng, 1ng, 500pg, 100pg, 50pg, or 20pg of DNA in each reaction. Overall, few alleles failed to exceed a 70rfu threshold in 1ng samples, less than half the alleles failed to cross this threshold in 500pg samples, and alleles did not amplify in 100pg samples.

In conclusion, this STR multiplex reaction is efficient for use in teaching and research laboratories. The low cost of approximately \$0.50 per reaction makes this an attractive option for labs when producing a rare profile specific to an individual is not necessary. Peak imbalances may occur with individual preparations of primer mix, which can be corrected by adding additional primers for the low locus. Also, this reaction is not as sensitive as reactions using a commercial kit.

STR Multiplex, Education, DNA

B75 Whole Genome Amplification as a Potential Means for Sample Immortalization

Valerie Clermont Beaudoin, BS*, 1930 37th Street, NW, Washington, DC 20007; Katherine B. Gettings, PhD, NIST, 100 Bureau Drive, Mail Stop 8314, Gaithersburg, MD 20899; and Daniele S. Podini, PhD, Department of Forensic Science, 2100 Foxhall Road, NW, Washington, DC 20007

After attending this presentation, attendees will better understand the evaluation of Whole Genome Amplification (WGA) for DNA sample archiving.

This presentation will impact the forensic science community by highlighting the pros and cons of using WGA to generate abundant quantities of DNA from samples that are currently in limited amounts. Specifically, this study was designed for a database of samples that have been collected as part of the National Institute of Justice-funded research, with ancestry and phenotypic information of the donors. The *immortalization* of these samples will allow sharing them with other researchers to improve ancestry and phenotype prediction models.

The availability of high-quality DNA from the aforementioned samples is limited, as only three cheek swabs were collected per individual. A potential solution to this problem is the use of WGA to increase the concentration of DNA extract. To determine if WGA is a viable solution for maintaining reference samples of limited quantity, the most important parameter is whether WGA can yield a complete and balanced representation of the markers to be genotyped, be it Short-Tandem Repeats (STRs) or Single Nucleotide Polymorphisms (SNPs).

In this study, the REPLI-g® Mini Kit (a strand displacement-based amplification incorporating ϕ 29 polymerase) was used to amplify DNA extracted from buccal swabs. Five samples were amplified in triplicate with an input of 2ng while 23 samples were amplified singly with an input of 10ng (the amount recommended by the manufacturer). The amplified product was quantitated using multiple methods: Quantifiler® Human; Quantifiler® Trio; and, an in-house TaqMan® assay targeting a single copy region on Chromosome 5. Quantitation results varied significantly with the three methods, suggesting that the WGA process amplifies the targets of the three TaqMan® assays with varying efficiency. Based on Quantifiler® Human results, WGA yielded an average of 250ng of DNA from a 10ng input (ranging from 28ng to 900ng), whereas with a 2ng input, the reaction yielded an average of 54ng (ranging from 4ng to 208ng). Two samples with an input of 10ng and one sample with an input of 2ng failed to amplify.

The WGA product was then amplified with AmpfSTR® Identifiler® Plus using 0.3ng of input DNA (based on Quantifiler® Human results) in a 5 μ L reaction volume (conditions optimized for reference samples at George Washington University (GWU)). The WGA product was also genotyped at 50 SNP loci, using SNaPshot® assays developed at GWU with 2ng of input DNA (based on Quantifiler® Human results). Off-scale peak heights and split peaks were obtained from the Identifiler® Plus amplification products, suggesting a possible Quantifiler® Human underestimation of the WGA yield in respect to the STR regions targeted in the assay. This issue is being further investigated.

For WGA-DNA input levels of both 10ng and 2ng, one allele dropped out per profile on average. All profiles showed locus-to-locus imbalance. The average peak height ratio between sister alleles in the 10ng samples was higher than in the 2ng samples. The 2ng triplicates yielded a full consensus profile although each replicate contained one instance of drop out. Of the tested SNPs, 49/50 were successfully genotyped; the failed SNP also failed in the original (non-WGA) DNA extract, possibly due to PCR primer efficiency issues. All peaks were present and distinguishable from artifacts/noise and genotypes were consistent with those obtained from the original DNA extracts.

According to the results obtained, WGA is a promising solution for sample archiving, although caution must be exercised. In this experiment, SNPs appeared more robust than STRs. Further studies evaluating a larger panel of markers with Next Generation Sequencing (NGS) technology, and evaluating higher levels of input DNA, will better assess the potential of WGA for sample immortalization.

As technology rapidly progresses, it is likely that in the foreseeable future new and comprehensive methods for high-level multiplexing of multiple marker types will be available to the forensic community. Thus, future availability of these well-characterized samples will be increasingly important in the development of methods and interpretation guidelines for ancestry and phenotype prediction.

WGA, SNPs, Sample Archiving

B76 Highly Multiplexed Analysis of STRs and SNPs Using Massively Parallel Sequencing: Concordance With Current Methodologies

Whitney A. Simpson, BS, 4123 Roundtree Road, Henrico, VA 23294; Carey P. Davis, MS, 1150 21st Street, #6, San Diego, CA 92102; Cydne L. Holt, PhD, 1841 Wilstone Avenue, Encinitas, CA 92024; Tracey Dawson Cruz, PhD, Virginia Commonwealth University, 1015 Floyd Avenue, PO Box 843079, Richmond, VA 23284; and Kathryn Stephens, 5200 Illumina Way, San Diego, CA 92122*

After attending this presentation, attendees will be informed about next generation sequencing applied to forensic DNA analysis and whether data generated from sequencing is concordant with capillary electrophoresis data.

This presentation will impact the forensic science community by exploring the advantages of Next Generation Sequencing (NGS) to forensic DNA analysis as well as its concordant results with current methodologies.

Capillary Electrophoresis (CE) is the predominant method for DNA analysis currently employed by forensic laboratories and has been regarded as the gold standard for many years. Data from this technique has been admitted into court since 1996. Although this is an effective technique, it is limited in the amount and type of information that can be generated efficiently. Although Short Tandem Repeats (STRs) can give sufficient information for human identification, it is often useful in forensic cases to be able to analyze other variants including Single Nucleotide Polymorphisms (SNPs) and Y-chromosomal Short Tandem Repeats (Y-STRs), which can provide valuable information to law enforcement. Analyzing SNPs using CE is difficult due to multiplexing constraints and is not often performed in forensic laboratories.

Whole Genome Sequencing (WGS) is now more widely available with the advent of NGS techniques. WGS allows analysts to analyze STRs as well as other informative variants in the DNA sequence simultaneously. With NGS systems, scientists are able to obtain an accurate sequence of a genome in a relatively short amount of time due to the massively parallel sequencing that is utilized by NGS platforms. Each base is sequenced 30 or more times to ensure accurate calls are being made. NGS can also be used for targeted sequencing to study specific genetic regions of interest according to application.

As technology continues to expand, it would be useful to consider if these advanced technologies could help forensic laboratories gain more information from their often difficult and limited samples. Illumina's® Prototype ForenSeq™ DNA Signature Prep Kit is an NGS kit targeted for forensics. With this system, one workflow is required to analyze a multitude of variants including autosomal STRs, SNPs (identity, phenotype, and ancestry informative), Y-STRs, and X-chromosomal Short Tandem Repeat (X-STRs). The kit targets all STRs required for the Combined DNA Index System (CODIS) and European Standard Set (ESS) of STR loci, as well as many more. Because of the system's ability to distinguish indexed samples, 32 to 96 samples also can be run concurrently with NGS on a single run. This approach could tremendously impact existing backlogs in forensic laboratories. Sequencing by NGS has the advantage of being able to analyze more loci at a time, thereby generating more information for the analyst.

This study was performed to check concordance of sequencing data performed on Illumina's® MiSeq™ FGx using the Prototype ForenSeq™ DNA Signature Prep Kit against data obtained using traditional CE methods. Concordance was also checked between SNP data from the Prototype ForenSeq™ kit against Illumina's® WGS data from the Platinum Genome Project. This study focused on concordance between the 95 identity informative SNPs, 29 autosomal STRs, 9 X-STRs, 24 Y-STRs, 22 phenotypic informative SNPs, and 56 ancestry informative SNPs that are included in the Illumina's® Prototype ForenSeq™ DNA Signature Prep Kit. Full profiles were generated for all 23 samples run simultaneously with the Prototype ForenSeq™ DNA Signature Prep Kit. A total discordance of 0.001% was observed for this study. Showing concordance between this new technology and the existing technologies would confirm the possibility of implementation of the ForenSeq™ DNA Signature Prep Kit into forensic laboratories.

Next Generation Sequencing, Concordance, Forensic DNA Analysis

B77 Evaluation of a Novel Material, Diomics X-Swab™, for Collection of DNA

Pamela L. Marshall, PhD, Southern University at New Orleans, 6400 Press Drive, New Orleans, LA 70126*

After attending this presentation, attendees will better understand the current issues associated with DNA collection and recovery and the exacerbation of these issues in low copy number DNA analysis. Attendees will be provided with information on a new collection device for DNA and the results of an experimental study to gain an appreciation of the critical role collection devices play in forensics.

This presentation will impact the forensic science community by making attendees aware of critical issues in DNA collection and recovery and by providing information on a novel collection device which offers a potential solution.

Success of DNA typing is related to the amount of target material recovered from an evidentiary item. Generally, the more DNA that is recovered, the better the chance of obtaining a typing result that will be robust and reliable. One method of collecting stain materials is by swabbing. Recovery of DNA from a number of commercially-available swabs is not an efficient process. The X-Swab™ is a unique bio-specimen collection material which can be dissolved during certain extraction conditions. Therefore, more DNA may be collected from a substrate and be released from the swab matrix than other swabs. The ability to recover DNA from the X-Swab™ and success in Short Tandem Repeat (STR) typing were compared with the Copan 4N6FLOQSwab™, a device which utilizes a proprietary flocked-swab technology to maximize DNA collection and elution efficiency. Both types of swabs were impregnated with known amounts of DNA and body fluids (replicates of 10) and allowed to air dry. In addition, blood was placed onto glass slides (replicates of 10), allowed to dry, and collected using both types of swabs. DNA recovery was assessed by DNA quantitation and by STR typing. X-Swab™ material had a significantly higher DNA recovery at the 1:10 (p value=0.008) and 1:50 dilutions of whole blood (p value= 2.1×10^{-7}). For dilutions of saliva, a significantly higher DNA yield was observed for X-Swab™ material for the 1:5 (p value= 1.1×10^{-7}) and 1:10 dilutions (p value=0.002) compared with DNA recovery from the 4N6FLOQSwab™. For the 1:10 dilution bloodstains, the X-Swab™ and the 4N6FLOQSwab™ had very similar average DNA yields ($62\text{ng} \pm 17$ and $73\text{ng} \pm 27$, respectively; p value=0.82), even though the X-Swab™ surface area and volume were considerably smaller. For the 1:100 dilution stains, the X-Swab™ yielded nearly twice as much DNA ($6.6\text{ng} \pm 1.5$) as the 4N6FLOQSwab™ ($3.6\text{ng} \pm 1$), but the difference in yield was not significant (p value=0.30). Partial or full STR profiles were obtained for all samples for both swab types at both dilutions using the PowerPlex® ESI 17 Pro System. For both the 1:10 and 1:100 dilutions, the X-Swab™ yielded higher Relative Fluorescence Units (RFU) values at all loci. The results demonstrated that the X-Swab™ material yielded greater DNA recovery, particularly of low quantity samples, compared with the 4N6FLOQSwab™. Results also indicated that the X-Swab™ material itself enhanced yield of PCR products.

DNA Collection, DNA Recovery, Diomics X-Swab™

B78 Assessing the Forensic Potential of Small Arms Propellant Micromorphometry as an Aid in the Investigation of Improvised Explosive Devices (IEDs): A Pilot Study

*Jack Hietpas, PhD**, 1617 Courthouse Road, Stafford, VA 22554-5409; and *Peter J. Diaczuk, BS*, 445 W 59th Street, New York, NY 10019-2925

After attending this presentation, participants will have a better understanding of the strengths and limitations of morphometry as a method for the characterization and discrimination of small arms propellants.

This presentation will impact the forensic science community by demonstrating the application of automated image analysis for the measurement of small arms morphometry as a quantitative method for the characterization of explosives.

Pipe bombs are the most common IED in the United States, with the majority containing small arms propellant (Smokeless Powder (SP) and Black Powder (BP)) as the main explosive charge.¹ In addition, United States and coalition war fighters combat IEDs at an unprecedented scale.² Thus there is a need to develop robust metrics for the characterization of propellants that are used as explosives as well as for comparisons between exemplar and recovered explosive residues. SP micrometry (length and width measurements) has been shown to help reduce the number of possible manufactured brands, thus providing fast, valuable investigative information.¹

In this pilot study, the potential to use automated image analysis software to characterize small arms propellants was investigated. Approximately 50 samples of SP and BP were acquired. These samples consist of eight propellant distributors and span 37 brands. In addition, there are several sample brand replicates that have either different production dates or different distributors. For each sample, at least 100 kernels of powder were placed on transparent adhesive backings. Transmitted light was used to produce high-contrast “masks” of the individual kernels. Photomicrographs were captured at 10-30x magnification using stereomicroscopy. Open-source image analysis software was used to process the propellant kernel images, thus allowing thousands of particles to be quickly characterized. The following parameters were measured for all the particles in each captured image: area, perimeter, major and minor axis of best fit ellipse, circularity, porosity, aspect ratio, and solidity. Canonical Discriminant Analysis (CDA) was used to separate the sample classes. These classes were treated as a database of known standards. Next, an independent set of particles was processed (from the original stock propellant samples). These were treated as “unknown” samples. These “unknowns” were assigned to the class (database entry) that had the smallest Mahalanobis distance. Seven samples were incorrectly assigned to the specific database entry; however, two of these were simply assigned to replicate entries (same brand, different lot or distributor). In addition, two of the incorrect samples were assigned to database entries that have been reported to be the same propellant but sold under different brand names. The remaining three samples were truly incorrect assignments. The results from this study show that there is potential for using automated image analysis for the characterization of small arms propellants. By using automated methods, the time required for particle measurements is dramatically reduced in comparison to manual methods.

Image Analysis, Smokeless Powders, Explosives

B79 Integration of the QIAcube® Into the Laboratory Workflow for Efficient Processing of Sexual Assault Casework

Michelle L. Collins Gaines, MSFS, Alaska Scientific Crime Detection Laboratory, 4805 Dr Martin Luther King Jr Avenue, Anchorage, AK 99507; and Cheryl M. Duda, MS, Alaska Scientific Crime Detection Laboratory, 4805 Dr Martin Luther King Jr Avenue, Anchorage, AK 99507*

After attending this presentation, attendees will learn how the Qiagen® QIAcube® was implemented into the workflow for processing of sexual assault cases and how they may be able to modify their own laboratory's workflow to gain efficiency.

This presentation will impact the forensic science community by demonstrating how many laboratories struggle with DNA backlogs and showing how to increase throughput without an increase in staffing. The changes detailed in this presentation may assist laboratories in addressing their own DNA backlogs.

The Alaska Scientific Crime Detection Laboratory has historically separated processing of forensic casework into two distinct services of biological screening and DNA analysis. Biological screeners would examine evidence to identify samples/stains that were appropriate for DNA testing based on the results of presumptive chemical tests and microscopic examinations for spermatozoa. A DNA analyst would then resample an item and begin work at the DNA extraction phase, repeating microscopic examinations to assess the efficacy of the differential DNA extraction for sexual assault evidence. This workflow has been inefficient in that two people are independently opening, documenting, sampling, and sometimes performing microscopic exams of the same item.

The laboratory has recently completed validation of the QIAcube® and modified the workflow for sexual assault evidence to eliminate redundancy and maximize the utility of the information provided by the presumptive chemical tests and the DNA quantification. These changes will lead to many samples being extracted and quantified with no prior screening and significantly fewer microscopic examinations being performed. Additionally, the biological screener will be performing the extraction and quantification. A DNA analyst will pick up the case at the amplification stage and carry it through the remainder of the processing.

Several positive outcomes are expected as a result of the new instrumentation and workflow for sexual assault cases. These changes will decrease the turnaround time for DNA cases and increase the throughput of the laboratory. By eliminating the redundancy of tasks between the biological screener and the DNA analyst, the time required to prepare samples for DNA extraction will be cut in half. The DNA extraction process itself, formerly a three-day process that included two overnight soak/digest steps, can now be completed in one day.

Historically, DNA analysts were selecting samples based on the forensic history provided by the alleged victim, the results of presumptive chemical tests, and microscopic examinations; however, these test results are not as predictive of successful typing results as human and male quantification results. Furthermore, it has been observed that even after an aggressive digestion of the cellular material on casework, a significant number of sperm cells remain on the substrate, often greater than what was removed during the extraction protocol. Analysts are now routinely performing a Dithiothreitol (DTT) digest of substrates in addition to the sperm fractions generated on the QIAcube® and quantifying all three samples (epithelial, sperm, and substrate). Armed with quantification results, DNA analysts are able to make better informed choices when selecting samples for amplification and typing, minimizing the need to perform additional testing when the initially processed samples do not yield probative DNA typing results.

Although the laboratory has only recently gone online with the modified differential workflow, the initial results are promising. Compared to the previous (manual) differential method, the QIAcube®-facilitated extractions generally yield more single-source sperm (and/or substrate) fractions and the yield of male DNA in these fractions has been observed to be higher with the QIAcube® than with the manual method. Furthermore, samples processed with the QIAcube® have been observed to yield interpretable sperm fractions even when the microscopic exams did not result in the observation of spermatozoa. It is anticipated that the laboratory will now obtain probative male DNA profiles in cases which may not have proceeded to DNA when the laboratory relied on microscopic exam results for DNA sample selection.

B80 The Evaluation of the Qubit® 2.0 Fluorometer Quantitation System and Comparison to Real-Time Quantitative PCR

Lisa Burgee, MSFS, 901 R.S. Gass Boulevard, Nashville, TN 37216; Miles W. Fisher, U.S. Air Force Academy, 2304 Cadet Drive, Colorado Springs, CO 80840; Kazufusa C. Okamoto, PhD, Defense Forensic Science Center, 4930 N 31st Street, Forest Park, GA 30297; Karen Olson, PhD, Defense Forensic Science Center, 4930 N 31st Street, Forest Park, GA 30297; and Roman Aranda IV, PhD, Defense Forensic Science Center, Office of the Chief Scientist, 4930 N 31st Street, Forest Park, GA 30297*

After attending this presentation, attendees will understand the basic functionality of the Qubit® 2.0 Fluorometer and how the instrument compares to current real-time Polymerase Chain Reaction (PCR) technology in terms of cost, time required, and accuracy of the results.

This presentation will impact the forensic science community by providing a comparison between quantitation methods currently employed by forensic laboratories and a newer fluorescence-based method, the Qubit® 2.0 Fluorometer, which is currently being used in the next generation sequencing workflow.

Real-Time quantitative PCR (RT-qPCR) is the current forensic method to determine the concentration of human DNA and is accurate, reliable, human-specific, and has a high degree of sensitivity; however, the method is time consuming, typically requiring two hours, and relies heavily on the accuracy of the serially diluted standards. As the field of DNA quantification advances, new methods that can accurately quantify the DNA more efficiently and without using a large amount of the sample could potentially replace RT-qPCR in forensic laboratories. The Qubit® 2.0 Fluorometer is a fluorescence-based quantitation system that measures the concentration of double stranded DNA (dsDNA) with a detection range between 10pg/μL and 1,000ng/μL; however, the assays are currently not human-specific and measure the total amount of dsDNA that is present in a sample.¹

This study compares the quantitation values of a sample when measured by the Qubit® and the Plexor® HY kit with an Applied Biosystems® 7500 Real-Time PCR System. Fifteen anonymous donors provided buccal swabs for use in the study. DNA from each sample was extracted using the “tip dance” protocol of the EZ1 Advanced robot and an initial quantitation value of the samples was determined using the Qubit® instrumentation. A dilution was made based on the resulting concentration to target 5ng/μL or 2ng/μL, depending on the starting concentration of the extracted DNA sample. This was followed by a serial dilution to produce a range of concentrations in order to test the limit of detection of the two Qubit® Assay kits: High Sensitivity (HS) and Broad Range (BR). The HS Assay kit is accurate for initial concentrations of 10pg/μL to 100ng/μL, while the BR Assay kit is accurate for 100pg/μL to 1,000ng/μL. The same dilutions were used with both the HS and BR kits. For comparison, the same samples were quantified using the Plexor® HY system. The results indicated that the Qubit® BR Assay kit is not ideal for forensic samples as it is unable to read samples with concentrations below 1ng/μL when using 2μL of sample to quantify the sample. The HS kit was much more consistent reading the samples that had concentrations below 1ng/μL. When the quantitation values generated by the Qubit® were compared to those of RT-qPCR, it was evident that RT-qPCR was more sensitive when small amounts of DNA were present in the sample. After capillary electrophoresis, the peak heights on the electropherograms were analyzed for the amplification reactions targeting 1ng (or 1,500 Relative Fluorescence Units (RFU) per allele) based on the Qubit® and RT-qPCR quantitation values. The average RFU value for the samples quantified using the Qubit® was 1,588±313 and the average RFU value for the RT-qPCR was 1,080±434 RFU per allele and Qubit® variance was 20% while the RT-qPCR variance was 40%, thus indicating that the Qubit® yielded results as consistently as RT-qPCR-derived profiles and more closely to the desired 1,500 RFU per allele.

The short amount of time needed to quantify a sample, along with the low cost, would make the Qubit® useful in forensic laboratories. The Qubit® takes less than five seconds to determine the concentration of a sample, thereby allowing analysts to quantify a large number of samples in a relatively short amount of time. It costs less than \$1.00 to run a sample on the instrument and is cheaper than the reagents currently required for use with the Applied Biosystems® 7500 (~\$3.00 per reaction); however, based on the results of this study, RT-qPCR is still more sensitive when directly compared to the Qubit®, and specificity for human DNA is required for implementation in forensic laboratories according to the Quality Assurance Standards for Forensic DNA Testing Laboratories published by the Federal Bureau of Investigation.

Qubit®, DNA Quantitation, Comparison

B81 White-Light Versus Shortwave-Ultraviolet Illumination for Visualizing Fingerprints Developed With Columnar Thin Films of Alq3

Stephanie Plazibat, BA, 107 Whitmore Laboratory, University Park, PA 16802; Stephen Swiontek, Pennsylvania State University, 212 EES Bldg, University Park, PA 16802; Akhlesh Lakhtakia, PhD, DSc, 212 EES Bldg, University Park, PA 16802; and Reena Roy, PhD, Pennsylvania State University, Forensic Science Program, 325 Whitmore Lab, University Park, PA 16802*

After attending this presentation, attendees will understand how to appropriately illuminate fingerprints developed with Columnar Thin Films (CTFs) of Tris(8-hydroxyquinolino) aluminum, commonly known as Alq3, for visualization.

This presentation will impact the forensic science community by alerting forensic scientists to a currently emerging technique of fingerprint development that may be more valuable than conventional techniques. It will also act as a guide to clarify the appropriate illumination procedures in documenting and analyzing fingerprints that have been developed with Alq3 CTFs. It has previously been believed that shortwave-ultraviolet illumination was best suited to obtain the most detail in fingerprints developed with Alq3 CTFs, but it is hypothesized that white-light illumination will provide as good, if not better, detail in photographs of the developed fingerprints.

The CTF technique preserves the topology of the fingerprint. A CTF is a collection of parallel nanoscale columns. These columns are grown upright atop the fingerprint residue.

In this study, CTFs were deposited on partial bloody fingerprints laid on brass substrates. Brass is a forensically relevant material, being used in such items as cartridge casings and household items. The CTF material used was Alq3, which has an absorption band centered at 259nm, and two fluorescence bands centered at 390nm and 519nm. According to Muhlberger et al., a fingerprint developed by the deposition of an Alq3 CTF is best visualized with illumination by shortwave-ultraviolet light.¹ The goal of this study is to determine which type of illumination is better in order to image the best detail of the fingerprint: white-light or shortwave-ultraviolet illumination.

To accomplish this goal, the partial bloody fingerprints on brass were developed by the CTFs of Alq3, then photographed using different sources of illumination. The quality of the fingerprints after deposition was graded objectively and subjectively. The objective grading was performed using a combination of three software programs that ultimately assigns a percentage score to the fingerprint based on the amount of definitive minutiae. The subjective grading was performed by visual examination and assignment of a score based on the clarity of ridge flow and minutiae.

Initial observations suggested that both the white-light and shortwave-ultraviolet illumination resulted in good-quality photographs of the partial bloody fingerprints. After objective grading of the photographs, white-light illumination is significantly better than shortwave-ultraviolet illumination. Subjective grading also shows a similar trend.

Thus, experiments have shown that contrary to previous knowledge, fingerprints developed by Alq3 CTFs can be better visualized through the use of white-light illumination than shortwave-ultraviolet illumination. Use of the correct type of lighting will allow for better-quality photographs of the developed fingerprints, which is important for identification.

B82 The Effect of Walking on the Evidentiary Value of Soil Taken From Footwear

*Heather T. Moody**, 265 N Saint Lucas Street, Apt 1, Allentown, PA 18104; and *Lawrence Quarino, PhD*, Cedar Crest College, Dept of Chemistry & Physical Science, 100 College Drive, Allentown, PA 18104

After attending this presentation, attendees will understand how soil analysis from footwear is impacted by distance traveled from the point of origin of the soil.

This presentation will impact the forensic science community by demonstrating the validity of comparisons between soil samples taken at a point of origin and that found on footwear that has been walked on up to 1.5 miles after transfer.

Evidentiary 3D footwear indentations are often casted using a form of dental stone. The cast can then be compared to the exemplar footwear using identifying and individualizing characteristics; however, if the cast does not provide sufficient detail to make it useful in an investigation, scientists may examine adhered soil to the cast in the event that evidentiary footwear is found. Examination of soil from both the cast and the collected footwear may be performed using several methodologies. These analyses include pH, organic loss on ignition, palynology, particle size distribution, mineralogy, and elemental composition. Particle size distribution is particularly probative because it directly relates to the mineral content which in turn directly relates to the elemental composition. In order for a comparison between soil in the footwear and soil adhering to the cast (at least at the point of origin) to be valid, the composition of the soil in the footwear must not be changed as a result of the impact of the footwear with surfaces after transfer. To date, no research has been performed to see if the characteristics of soil in footwear change between transfer and collection. This study examines this question by determining whether the particle size distribution of soil in footwear is altered while walking on an asphalt surface as a function of distance.

Soil was collected along a tree line, mixed, and homogenized. Particle size distribution was performed on five samples of the soil using a previously published method.¹ Cumulative weight graphs were generated from size fractions weighed after sieving with mesh sizes measuring 2,000 μm , 500 μm , 250 μm , 125 μm , and 63 μm . These results served as the zero-mile trial, representative of the point of origin or site of casting. Soil from the same sample was moistened and applied to the grooves of sneakers (by stepping into the soil) from two volunteers weighing 110 and 130 pounds, respectively, and collected after each of five trials at four walked distances (0.5, 1, 1.5, and 2 miles) on dry asphalt. The same type of sneaker was worn by both volunteers. After each trial, soil remaining on the treads of the sneakers was collected from four regions — right heel, right toe, left heel, and left toe — and approximately 1.2g of the soil was analyzed using the particle size distribution method and compared against the zero-mile trial. Mean cumulative weight graphs were converted to semi-log graphs from soil collected from each region of the sneaker from both volunteers at each distance and compared to mean semi-log graphs generated from the zero-mile trial. The Kolmogorov-Smirnov test, a non-parametric statistical test, was used at the 95% confidence interval to determine differences between the semi-log graphs from the zero-mile samples and the distance trials. This test showed that all (ten out of ten) of the 0.5-mile trials, eight out of ten one-mile trials, and nine out of ten 1.5-mile trials were indistinguishable from the zero-mile samples. Of the two differing one-mile trials, only one region out of eight was found to be indistinguishable from the zero-mile samples. Of the single differing 1.5-mile trial, one-half of the regions were found to be indistinguishable from the zero-mile samples. The two-mile trials did not yield enough soil for analysis.

Although several other parameters need to be examined (different weights of volunteers, running, different surfaces), results of the present study show that false exclusions are not likely to occur when comparing soil from footwear from a point source after walking a distance of up to 1.5 miles.

False Exclusions in Soil, Footwear, Particle Size Distribution

B83 Characterization of Solder by Trace Metals Using Atomic Absorption Spectroscopy (AAS)

Sean T. Block, BS, 75 Holland Road, Wantage, NJ 07461; and Lindsey A. Welch, PhD, Cedar Crest College, 100 College Drive, Dept of Chemical and Physical Sciences, Allentown, PA 18104*

After attending this presentation, attendees will understand: (1) an available method for analyzing solder using AAS; (2) some of the information that may be obtained from trace elemental analysis of solder; and, (3) potential issues in using solder elemental profiles for investigative purposes and as prosecutorial evidence.

This presentation will impact the forensic science community by providing insight into the use of solder as a potential investigative tool in criminal cases that involve improvised explosive devices and/or handmade electronic circuits and fuses.

Trace elemental analysis is capable of characterizing materials found during an investigation and identifying a potential source. This includes potentially linking the evidence to a known brand, lot, or sample of a given product. As a consequence, this technique can provide investigators with valuable knowledge about evidence present at a crime scene. Solder is a relatively common and easy-to-obtain material and is likely to be used in the construction of improvised explosive devices. Rapid analysis of solder found on either exploded shrapnel or undetonated devices may provide investigators with early leads as to the origins of the device and possible primary suspects as well as evidence against the suspect in the case of a trace profile match.

This study employs a method for rapidly digesting and analyzing samples via AAS. Twelve distinct brands of 60/40 tin/lead solder were digested in hydrochloric and nitric acids. Analysis of sample digestions was targeted at identifying differences in trace element concentrations between samples. To examine consistencies within brands, three separate spools each of several brands were analyzed. While other methods for analyzing solder using inductively-coupled plasma sampling techniques have been proposed, AAS is currently more commonly found in forensic laboratories, which would allow for a more facilitated processing of solder samples. A rapid response and dissemination of information pertinent to identifying suspects is critical in cases involving explosives evidence.

This study will present measured concentrations for copper, silver, and bismuth in several commercially available solder samples. Discriminant analysis of these trace profiles suggest that differentiation of solder samples by as little as three elements is possible using AAS according to the proposed method. Sample identification based on trace element concentrations generally had an accuracy of >90%; however, identifying the brand of solder from a given trace element profile is much less accurate. Overall, this study indicates that AAS identification of solder by a direct comparison of an unknown sample to an exemplar may be performed with a high level of accuracy.

Trace Elements, Solder, AAS

B84 Surface-Enhanced Raman Spectroscopy for Forensic Analysis of Human Semen

Jessica Irvine, BS*, Boston University School of Medicine, 72 E Concord Street, Boston, MA 02118; Jennifer Fore, PhD, Boston University, Photonics Center-Dept of Chemistry, 8 St Mary's Street, Boston, MA 02118; Ranjith Premasiri, PhD, Boston University, Dept of Chemistry, 590 Commonwealth Avenue, Boston, MA 02215; Lawrence Ziegler, Boston University, Dept of Chemistry, 590 Commonwealth Avenue, Boston, MA 02215; and Amy N. Brodeur, MFS, Boston University School of Medicine, 72 E Concord Street, R806, Boston, MA 02118

The goal of this presentation is to provide attendees with a general understanding of a common vibrational spectroscopic technique known as Surface-Enhanced Raman Spectroscopy (SERS) and how it can be used to identify an unknown stain such as semen and mixtures of semen with other body fluids. The protocols established in order to obtain reproducible results and the reasoning behind variations present between liquid and dried samples will be presented.

This presentation will impact the forensic science community by discussing how these preliminary studies and methodology development for semen identification via SERS demonstrate a potential new tool for the analysis of stains relevant to sexual assault cases. As research in this field progresses, reliable identification of additional body fluid stains is highly likely. This could greatly reduce the effort expended to analyze unknown samples, save the forensic community time and money, and establish a single confirmatory identification method for all human body fluids.

Identification of an unknown stain encountered at a crime scene, especially where the context of the case does not provide an indication of the identity of the stain, currently requires a number of time-consuming and costly presumptive and confirmatory tests be performed. SERS is a vibrational spectroscopic method that could allow crime scene analysts to rapidly identify unknown stains both in the laboratory and in the field. The SERS technique utilizes a laser which interacts with molecules applied to a gold nanoparticle chip (SERS substrate) that enhances the normal Raman signal, producing a shift in energy characteristic of the vibrational modes present. These shifts are detected as peaks and the combination of peaks provides the analyst with a unique spectral fingerprint of the molecular components of the sample. The advantages of this method include its high sensitivity, speed, non-destructive nature, ease-of-use, minimal sample preparation requirement, portability, and multiplexing capabilities.

In contrast to conventional Raman spectroscopy, SERS offers higher sensitivity resulting in small sample volumes (~1 μ L or less) being required for sample identification and the ability to process dilute solutions. This allows for the remaining sample to be utilized for other forensic tests, making the SERS technique an ideal analytical method for use at a crime scene.

It is hypothesized that SERS can be coupled with multivariate statistical methods and established as a confirmatory technique in the analysis of human body fluids encountered at a crime scene. While SERS has been explored for other applications such as analysis of drugs, bacterial diagnostics, and detection of single molecules, little research has been conducted to apply it to forensic analysis of human body fluids.¹⁻³ This investigation identified and characterized semen from a single donor: neat and neat stained on cotton swatches and swabs. All samples were measured in triplicate to ensure reproducibility and the SERS spectra were acquired using a 785nm laser excitation exposed for 10 seconds at 0.6mW. Ten spectra of each chip were taken, averaged, and then compared to one another. Analysis revealed two components of the semen spectra as hypoxanthine and xanthine. Using ordinary least squares analysis, the abundance of each was determined to be 0.34 \pm 0.10 and 0.76 \pm 0.16, respectively; residuals revealed the possibility of an unaccounted-for component(s).

A protocol was designed for the extraction of dried semen stains and application to the SERS chip, in which approximately 150 μ L of semen was pipetted onto a cotton swatch and allowed to dry for 24 hours. The semen was then extracted under various conditions by adjusting both the volume of water and the time elapsed of the cutting's exposure to water. This resulted in extractions using 5 μ L of water sitting for one, two, five, and ten minutes, and 10 μ L of water sitting for five and ten minutes. Optimal results were obtained when a small cutting of the stain was extracted in 5 μ L of water for five minutes.

Additionally, 1:1 mixtures of semen in combination with blood, saliva, urine, and vaginal fluid were evaluated. Resulting spectra were determined to be combinations of the body fluids present which can be procedurally pulled apart using ordinary least squares analysis. Overall, it was concluded that semen produces a spectral pattern that is consistent and readily distinct from blood, saliva, urine, and vaginal fluid.

Raman Spectroscopy, SERS, Semen Identification

B85 An Improved Method for Extraction of DNA From Envelopes

*Quentin T. Gauthier, BS**, 16 Longacre Court, Hockessin, DE 19707; *Odile M. Loreille, PhD*, 1413 Research Boulevard, Rockville, MD 20850; *Pamela J. Staton, PhD*, Marshall University Forensic Science MSFS & Center, 1401 Forensic Science Drive, Huntington, WV 25701; and *Charla Marshall, PhD*, Armed Forces DNA Identification Laboratory, 115 Purple Heart Drive, Dover AFB, DE 19902

After attending this presentation, attendees will have a basic understanding of how to approach envelope DNA extractions in order to maximize DNA yield.

This presentation will impact the forensic science community by offering a more robust method for extracting DNA from historic envelopes with commonly found laboratory reagents.

To identify the best protocol for obtaining human DNA from envelopes, two sample collection methods were tested, involving both non-destructive and destructive methods, differing digestion solution volumes were evaluated, and two DNA extraction methods were compared.

At the Armed Forces DNA Identification Laboratory (AFDIL), envelopes can be used as alternative reference samples to help in the identification process. Currently at AFDIL, envelope DNA extractions are completed by: (1) using a steam bath to open the envelope seal; (2) swabbing the envelope seal to collect epithelial cells deposited when the envelope was licked; and, (3) extracting the swab using an organic extraction and purification method (PCIA, butanol, and ultra-4 column). Mitochondrial DNA (mtDNA) is targeted from envelope DNA extracts because it offers a direct comparison with mtDNA profiles from skeletal remains when nuclear DNA often yields incomplete profiles. Due to the sensitive nature of mtDNA analysis, the steam bath method can yield inconclusive results and introduce contamination from individuals who have previously handled the envelope.

This study developed a new method that maximizes the quantity of authentic DNA recovered from envelopes. To mimic casework conditions, mock envelopes containing a known mtDNA sequence in the seal of an envelope and a different known mtDNA sequence on the outside of the envelope were created for experimentation. These mock envelopes were used to evaluate how the following variables affected nuclear and mitochondrial DNA yields: (1) the amount of digestion buffer and proteinase K volumes; (2) the type of sample collection (steam bath-swabbing vs. cutting); and, (3) the type of extraction — organic vs. QIAamp® DNA Investigator Kit on the QIAcube®. Nuclear DNA yield was assessed by Quantifiler® Duo and mtDNA quality was assessed by mitochondrial DNA sequence data.

By changing the sample collection method to a cutting, the average amount of nuclear DNA recovered from each sample increased by nearly 40pg/μl, with a standard deviation of 9.2pg/μl. Increasing the amount of extraction buffer in the organic extraction process caused a similar increase in the amount of usable DNA. The average DNA recovered from those samples increased by roughly 15pg/μl, with a standard deviation of 8.4pg/μl. Attempts to use the QIAcube® did not prove fruitful, as the increase in recovered DNA was roughly 12pg/μl, while the improved organic extraction was nearly 60pg/μl.

The results indicate that using a cutting of the seal, rather than a swabbing of the seal, yields higher quantities of both nuclear and mtDNA after organic extraction. Secondly, the results show that increasing the volume of digestion buffer from 500μl to 1,200μl increases the quantity of DNA obtained. A comparison with the QIAamp® DNA Investigator extraction protocol performed on an automated QIAcube® instrument revealed that the organic extraction method resulted in higher quantities of DNA. No evidence of mixtures was observed despite the attempts to mimic casework conditions, most likely due to the high quality of the DNA within each mock envelope seal.

Continued evaluation of the method will incorporate heirloom envelopes similar to those encountered by the AFDIL casework sections. Additionally, the effect of Ultraviolet (UV) irradiation will be assessed to minimize the levels of exogenous DNA while not causing significant harm to the DNA contained within the seal.

DNA Extraction, Envelope, Quantification

B86 Pairwise Comparisons as a Means of Validating Iraqi Muslim and Christian Allele Frequency Databases

*Nathaniel D. Adams, BS**, 2850 Presidential Drive, Ste 160, Fairborn, OH 45324; *Salwa J. Al-awadi, PhD*, Al-Nahrain University, Abo Nuwa's Street, Baghdad 10072, IRAQ; *Majeed A. Sabbah, PhD*, Al-Nahrain University, Abo Nuwa's Street, Baghdad 10072, IRAQ; *Ashley E. Marshall, Forensic Bioinformatic Services*, 2850 Presidential Drive, Ste 160, Fairborn, OH 45324; *Carrie Rowland, MSc*, 2850 Presidential Drive, Ste 160, Fairborn, OH 45324; and *Dan Krane, PhD*, 3640 Colonel Glenn Highway, Dept Bio Sci, Dayton, OH 45435

After attending this presentation, attendees will have a better understanding of Iraqi Muslim and Christian allele frequencies as well as an understanding of a novel approach used to examine population substructure using pairwise comparisons.

This presentation will impact the forensic science community by providing a method that can be an additional measure of validity for sample populations used to develop allele frequency databases. Due to the weight placed on DNA evidence in criminal trials as well as civil actions such as establishing paternity or identifying human remains, an additional test of the validity of allele frequency databases can be utilized.

A total of 542 individuals (395 and 147 self-identified Muslims and Christians, respectively) from Baghdad were genotyped at 15 Short Tandem Repeat (STR) DNA markers (D3S1358, vWA, FGA, D8S1179, D21S11, D18S51, D5S818, D13S317, D7S820, TH01, TPOX, CSF1PO, D19S433, D2S1338, and D16S539) using the AmpFISTR® Identifier™ Polymerase Chain Reaction (PCR) Amplification Kit from Applied Biosystems®. Thirty-two alleles previously unobserved in the Iraqi population were detected in these individuals.

Conventional tests for Hardy Weinberg Equilibrium (HWE) and pairwise Linkage Equilibrium (LE) were performed on these populations and suggested that they were suitable for generating allele frequencies to be used in forensic DNA profiling work within Iraq; however, samples of populations displaying unacceptably high degrees of substructure can pass tests for HWE and LE. As a further test of the possibility of high levels of population substructure, exhaustive pairwise comparisons of the individuals within the Iraqi Muslim and Christian populations (77,815 and 10,731, respectively) were also performed. The distributions of pairwise allele sharing among the populations of Muslims and Christians were roughly Gaussian. The extent of allele sharing between pairs of individuals within Muslim ($\bar{x}=9.30$, $s=2.30$) and Christian ($\bar{x}=9.60$, $s=2.37$) populations was comparable to what was observed in 100 repetitions of these analyses using populations of simulated individuals with the same allele frequencies [Muslim ($\bar{x}=9.35$, $s=2.31$) and Christian ($\bar{x}=9.67$, $s=2.34$)]. The slightly greater degree of average pairwise allele sharing within populations of simulated individuals than what was observed in the actual populations may be an artifact of the slightly greater number of homozygous loci in the actual populations and will be the subject of further analyses with other actual populations. The maximum number of shared alleles observed in pairwise comparisons of actual profiles was 22 of a possible 30, while comparisons of simulated individuals yielded shared alleles of ($\bar{x}=19.65$, $s=0.76$) for Muslims and ($\bar{x}=18.88$, $s=0.70$) for Christians across the 100 simulations of each, indicating that there are no specific pairs of individuals in the Christian or Muslim Baghdad populations that are very likely to be close relatives.

All loci across both populations show high Power of Discrimination ($PD \geq 0.81$). Two-parent expected Power of Exclusion (PE) is greater than 0.50 at all loci except CSF1PO and TPOX in both Baghdad Iraqi Muslims and Christians. Polymorphism Information Content (PIC) was found to be highest for the D2S1338 locus (PIC=0.87 and 0.86 in Muslims and Christians, respectively) and lowest for the TPOX locus (PIC=0.65 and 0.57 in Muslims and Christians, respectively) in both populations. The Combined Matching Probability (CMP) was estimated to be $1.29E^{-18}$ and $9.83E^{-18}$ for the Muslim and Christian populations, respectively.

Iraq, Pairwise Comparisons, Allele Frequencies

B87 Evaluation of a Modified DNA Extraction Approach for Improved Short Tandem Repeat (STR) Recovery From Severely Degraded Skeletal Elements

*Harrison Redd**, 1319 Park Street, Apt 2, Huntington, WV 25705; *Charla Marshall, PhD, Armed Forces DNA Identification Laboratory, 115 Purple Heart Drive, Dover AFB, DE 19902; Pamela J. Staton, PhD, Marshall University Forensic Science MSFS & Center, 1401 Forensic Science Drive, Huntington, WV 25701; and Odile M. Loreille, PhD, 1413 Research Boulevard, Rockville, MD 20850*

After attending this presentation, attendees will learn best practices for processing DNA extracts from degraded skeletal remains where the goal is to increase the purity and concentration of extracts for the purpose of improving the likelihood that more complete STR profiles will be generated.

This presentation will impact the forensic science community, particularly laboratories working on missing persons cases, by presenting a new way to purify and enrich skeletal remains extracts for nuclear DNA (nucDNA) while minimizing the amount of Polymerase Chain Reaction (PCR) inhibitors that co-purify with the DNA.

Degraded skeletal remains generally contain limited quantities of nucDNA and thus, DNA-based identification efforts often target the mitochondrial DNA (mtDNA) control region due to the relative abundance of intact mtDNA as compared to nucDNA; however, in many cases the discriminatory power of mtDNA is inadequate to permit identification and STR analysis becomes essential. Unfortunately, commercial STR kits such as the AmpFISTR® Yfiler® PCR Amplification kit, AmpFISTR® MiniFiler™ PCR Amplification Kit, and PowerPlex® 16 HS PCR Amplification Kit require input DNA quantities greater than what is typically extracted from highly degraded bone samples. As a result, amplification is generally unsuccessful when following the manufacturer's recommendations.

In 2013, a Low Copy Number (LCN) Yfiler® protocol was adopted by the mitochondrial DNA section working on remains from unaccounted-for individuals from past conflicts at the Armed Forces DNA Identification Laboratory (AFDIL). This LCN protocol requires an increased amount of Taq polymerase and more cycles during PCR amplification. To be reported, an allele must be observed above stochastic threshold in at least two out of three or more independent amplifications. This protocol has increased the success rate for generating four or more alleles (the minimum number of alleles needed to report out a sample) to 40%. Unfortunately, in many cases, STR profiles remain incomplete.¹

Currently, 0.2g to 0.25g of bone powder is digested with a demineralization buffer (0.5 M EDTA and 1% N-lauroylsarcosine) and proteinase K; concentrated with an Amicon® Ultra-4 Centrifugal Filter Unit and purified twice with the MinElute® PCR Purification kit. Preliminary optimization experiments started with increasing the amount of bone powder to 0.5g or 1.0g (two or four times in amount) which resulted in a non-linear increase in DNA yield. Therefore, one possible explanation for the low DNA yield observed with the addition of increased amounts of bone powder is the binding competition between DNA and humic acid for the silica membrane of the MinElute® column. The goal of this project was to increase STR typing success rates by increasing the DNA concentration from bone extracts by finding a way to limit the effects of humic acid binding competition.^{2,3}

Presented here is a protocol where multiple 0.2g to 0.25g bone powder samples were extracted, pooled, and concentrated in a way that limited humic acid competition for silica. The extracts were quantified and LCN Yfiler® amplified before and after pooling. Results show that pooling three or four extracts produces the most significant increase in alleles reported. This can also be seen in the table below.

Number of Extracts Pooled	Cases with Equal or Better Results	Total Number of Cases	Success Rate
Two	7	14	50%
Three	3	4	75%

Criminalistics Section - 2015

Four	8	9	88.9%
------	---	---	-------

B88 What Do You Get When You Mix a Double Helix With a Becke Line? A Forensic Family

Ann Marie Gross, MS, MN BCA, Forensic Science Lab, 1430 Maryland Avenue, E, Saint Paul, MN 55106; and Susan Gross, MSFS*, 1430 Maryland Avenue, E, Saint Paul, MN 55106*

The goal of this presentation is to present the story of a real forensic family.

This presentation will impact the forensic science community by providing an entertaining yet informative discussion on how two siblings have mentored each other, learned from each other, and impacted the forensic science community together.

The Gross sisters (Ann Marie and Susan) are two forensic scientists who have worked together at the same crime laboratory for 18 years. These sisters can be as different as DNA and trace evidence yet can work together, just as mitochondrial DNA and microscopic hair examinations work hand-in-hand. After working 26 and 20 years, respectively, in forensic science, the sisters not only have family at home but also in their workplace. Ann Marie Gross has spent 26 years working in forensic science at the Minnesota Bureau of Criminal Apprehension (BCA) Forensic Science Services Laboratory. Her career began in 1989 as DNA analysis was being introduced into the forensic arena and she has experience in all DNA technologies — from Restriction Fragment Length Polymorphism (RFLP) to Short Tandem Repeats (STRs) and mitochondrial DNA. Susan Gross has spent 20 years in forensic science, 18 of which have also been at the BCA; her career has involved working in drug chemistry and transitioned into trace evidence. Both have experience in crime scene processing and are currently supervisors in their respective disciplines. How did it happen that two sisters are both working in the exclusive field of forensic science AND in the same laboratory?

This presentation will tell the story of how they entered into the forensic field. “Who followed who?” is a question often posed to the two of them — are their stories the same? Also addressed will be how each has mentored the other and what they have learned from each other. Benefits of having a sibling work in the same field and in the same laboratory will be discussed and the disadvantages of working together will be presented, as well. The challenges of being on crime scenes together and working cases together, which has led to testifying in the same cases, will be described. Finally, research projects the two have collaborated on and future endeavors for the two sisters will be discussed.

Forensic Family, Siblings, Mentoring

B89 A Study of the Formation, Collection, and Microscopic Trace Material and Genetic Makeup of Household Dust Specimens

Nicholas Petraco, MS, 73 Ireland Place, Amityville, NY 11701; John Ballantyne, PhD, University of Central Florida, Dept of Chemistry, 4000 Central Florida Boulevard, Orlando, FL 32816-2366; Erin K. Hanson, PhD, PO Box 162367, Orlando, FL 32816; and Katherine Farash, BS, University of Central Florida, Forensic Science Graduate Prog, Biochemistry Track, PO Box 162366, Orlando, FL 32826*

After attending this presentation, attendees will recognize how typical household dust specimens (i.e., dust bunnies) are formed and how the fibrous components form a cage-like structure that acts as a snare which in turn entraps an array of human and animal hairs, natural and synthetic fibers, as well as an assortment of particulate materials. Attendees will learn various techniques and strategies for the collection and handling of household dust specimens. The quantity and quality of all the materials collected in household dust bunnies will be presented.

This presentation will impact the forensic science community by demonstrating the probative value of an underutilized yet extremely valuable form of probative physical evidence — household dust.

Over the last century, classic forensic science as developed and practiced by early forensic pioneers (e.g., Dr. Edmond Locard, Dr. Harry Söderman, Dr. Paul L. Kirk, and others) has demonstrated that trace evidence in the form of dust is a valuable source of non-biased probative evidence in criminal investigations. As Dr. Locard asserts in his early writings, trace materials found in dust can be used to identify the individuals involved in a crime, as well as reconstruct the event itself. In the past few years, several papers have been presented which demonstrate that household dust specimens may in fact be unique to a given location. To date, these studies have focused on developing a rapid, accurate, microscopic methodology for tabulating the fibrous materials such as animal and human hair and natural and synthetic fibers, as well as the particulates commonly found in household dust specimens. This study combines the developed microscopic methodology used in these prior studies with new methods used to extract and analyze the human DNA present within each household dust specimen. It is believed that the combination of these different approaches will greatly enhance the discriminating power, as well as the probative value, of household dust by enabling one to not only identify a location but to also identify its habitual occupant(s).

In this part of the combined study, the structure of household dust specimens, the mechanics of how these specimens formed, and simple techniques for their collection were researched. Simple traps were prepared and the dust specimens were observed as they formed over a range of time spans. The simplest traps were prepared by labeling a pre-cleaned microscope slide, photographing it, and placing it on the floor in the subject location. Next, strips of Gel-Film® were cut and affixed to pre-cleaned, labeled microscope slides. Additional dust traps were prepared by attaching one- to two-inch lengths of Scotch® Brand 3M® Double-Sided Tape to pre-cleaned, labeled microscope slides. Finally, dust traps were prepared by sticking 12mm-diameter, double-coated carbon tabs to pre-cleaned, labeled microscope slides.

As in the case of the simplest dust traps, the dust traps containing the adhesive media were photographed and placed on the floor in the subject location. All of the dust traps were allowed to freely collect dust as it settled naturally on their surfaces over a range of time spans. After the collection period, each specimen was recovered and packaged separately. A number of the dust specimens were examined microscopically and their contents tabulated on a dust tabulation sheet while others were analyzed for their human DNA content. Select specimens had both their trace material content tabulated and their human DNA analyzed. For example, trace material content tabulation for specimen No. 4a listed the following: red-, blue-, black-, and pink-colored cotton fibers; blue wool fibers; gray/black nylon fibers; colorless polyester fibers; red-colored acrylic fibers; human skin cells; stellate-shaped plant hairs; manila-colored paper fibers; and one tiny piece of green vinyl tape. Finally, the data from both the microscopic method and the DNA analysis were collected, tabulated, and evaluated.

The results of this combined study demonstrate that human DNA of sufficient quantity and quality can be recovered from household dust. The use of DNA profiles in combination with micro-chemical analysis of the non-biological material in dust bunnies should permit an identification of the room from which the dust originated as well as the occupier(s) of the room.

B90 Combined Genetic and Micro-Chemical Analysis of Household Dust as a Definitive Trace Identifier of a Room and Its Occupants

Katherine Farash, BS, University of Central Florida, Forensic Science Graduate Prog, Biochemistry Track, PO Box 162366, Orlando, FL 32826; Hayley O'Brien, BS, National Center for Forensic Science, PO Box 162367, Orlando, FL 32826; Erin K. Hanson, PhD, PO Box 162367, Orlando, FL 32816; Nicholas Petraco, MS, 73 Ireland Place, Amityville, NY 11701; and John Ballantyne, PhD, University of Central Florida, Dept of Chemistry, 4000 Central Florida Boulevard, Orlando, FL 32816-2366*

After attending this presentation, attendees will learn how household dust (i.e., dust bunnies) is analyzed for the presence of human DNA. The quantity and quality of human DNA in dust bunnies will be presented. Attendees will also learn enhanced micro-volume strategies for the analysis of human bio-particles identified in dust bunnies.

This presentation will impact the forensic science community by demonstrating the probative value of an underused form of physical evidence — household dust or dust bunnies.

The ultimate goal of trace forensic evidence in a criminal investigation is to identify the people, places, and things involved in the commission of the crime. A commonly found trace material that does not appear to be widely analyzed in operational crime labs at this time is household dust. This is unfortunate since the potential for identification, rather than merely association, with this type of evidence is a realistic possibility. Macroscopic dust bunnies appear to be a unique entangled conglomeration of fibers containing a variety of inorganic and organic particulates from the immediate environment. Dust bunnies are formed over a period of time due to air flow and they accumulate inside rooms (inside homes or the workplace), vehicles (e.g., in the trunk), and even in some outdoor locations. They can be transferred onto, for example, the clothing of a body that has been dragged across the floor prior to the body being taken away and deposited elsewhere. Thus, in principle, if one or more dust bunnies are found associated with a crime it should be possible to positively identify the room from which the dust bunnies originated; however, the probative value of the dust bunny would be enhanced not only if the room could be identified but also the habitual occupier of the room. This might be accomplished by sensitive DNA typing of the cellular material that is trapped inside the dust bunny (likely originating from the habitual occupier of the room).

In this study, dust bunny samples were genetically profiled using two approaches: (1) organic DNA extraction of whole dust bunny samples with standard and increased cycle number Short Tandem Repeat (STR) profiling; and, (2) “smart” analysis with the individual isolation of bio-particles present in the dust bunny samples using micro-manipulation and enhanced micro-volume direct-Polymerase Chain Reaction (PCR) STR profiling. Detectable amounts of human DNA were obtained in 73% (29/40) of the whole dust bunny samples evaluated. DNA profiles (from one to >30 alleles) were obtained in 55% (standard cycle number) to 98% (increased cycle number) of the 40 dust bunnies examined. While admixed DNA profiles were observed in numerous whole dust bunny samples (particularly with increased cycle numbers), highly probative single-source DNA profiles (random match probabilities >10⁶) were recovered in ~25% of the samples.

The use of enhanced micro-manipulation collection techniques and direct micro-volume DNA profiling from individually isolated bio-particles recovered from within the dust bunnies was evaluated (11 samples tested). DNA profiles were successfully recovered from all dust bunnies examined, with profiles ranging in quality and number of alleles. From the more than 600 bio-particle samples evaluated, DNA profiles (from one to >30 alleles) were obtained in ~30% of the bio-particles tested. This enhanced analysis also resulted in the recovery of mainly single-source DNA profiles (97% of the samples tested) with multiple donors identified in some specimens.

The results of these studies demonstrate that human DNA of sufficient quantity and quality can be recovered from household dust (i.e., dust bunnies). The use of DNA profiles in combination with micro-chemical analysis of the non-biological material in dust bunnies should permit an identification of the room from which it originated as well as the occupier(s) of the room.

Household Dust, Dust Bunny, STR Analysis

B91 The Influence of Distance, Depth, and Time on Forensic DNA Profiling of Soil Bacteria

James Hopkins, BA, Michigan State University, 560 Baker Hall, East Lansing, MI 48824; Ellen M. Jesmok, BS, Michigan State University, 560 Baker Hall, 655 Auditorium Road, East Lansing, MI 48824; and David R. Foran, PhD, Michigan State University, Forensic Science Program, 560 Baker Hall, East Lansing, MI 48824*

After attending this presentation, attendees will understand how the bacterial composition of soil changes over space and time and how this affects its traceability back to a particular location. Attendees will also learn that bacterial profiling of soil using next generation sequencing is a viable tool in criminal investigations by linking evidentiary soil to a crime scene.

This presentation will impact the forensic science community by elucidating how spatial and temporal factors affect the bacterial profiles of diverse soils. Next generation sequencing was employed to develop libraries of bacterial sequences which were compared using multiple statistical techniques to determine their effectiveness in assessing how these factors influence profiles.

Microbial profiling has the potential to individualize a soil sample through the identification and comparison of the tremendous variability that exists in soil bacteria. Next generation sequencing can detect sequence differences at the species or strain level, which is much more sensitive than previous profiling techniques, and allows better classification of the bacteria present in a soil sample. This technique is also becoming more timely and cost effective — important considerations for future implementation of soil bacterial profiling in the criminal justice system.

Temporal effects on bacterial profiles were tested by sampling three habitats: a chemically treated yard, an untreated yard, and a deciduous forest. Surface samples were collected once a day for four days, once a week for two weeks, and once a month for one year. Spatial effects on bacterial profiles were tested by collecting at a center sampling site and 5, 10, 50, and 100 feet from the center in the four cardinal directions. Soil depth was also sampled at the same yard and forest, and a different treated yard, at the surface and directly below at 1, 2, 5, 10, 20, and 60 inches. Sample sets were collected twice, six months apart.

DNAs were extracted using a MO BIO PowerSoil® kit, amplified with bar-coded universal 16S rRNA primers, and sequenced on an Illumina® MiSeq®. Sequence libraries were filtered to remove ambiguous bases, aligned to known bacterial sequences, and trimmed to the region of interest. Statistical pairwise comparisons were performed on all libraries in order to examine whether or not the bacterial profiles were significantly different from one another. Further, variation between libraries was calculated using Bray-Curtis dissimilarity index, which was visualized using a multivariate statistical approach to determine relationships among samples based on their placement in multidimensional space.

Surface soil samples collected from the same location over time associated with each other and also separated from other habitats, both pairwise and in multidimensional space. Spatially, pairwise comparisons and the multivariate statistic showed samples collected near the center point of a yard habitat shared similar bacterial profiles, which became more dissimilar as distance increased. In contrast, the forest samples displayed much more heterogeneity even at short distances. The depth samples showed a similar trend: samples collected at or near the surface (zero to five inches) were similar, but beyond that, bacterial profile differences existed.

The statistical measures largely agreed with each other throughout all comparisons. Multivariate evaluations are valuable as they allow a visual assessment of profile similarities and dissimilarities; however, they do not provide a specific statistical significance value. In contrast, pairwise comparisons can be used to determine significance, but the relationship among all samples is difficult to assess, especially when attempting to determine degrees of difference. Forensically, bacterial profiling of soil via next generation sequencing of 16S rRNA variable regions shows strong potential for tracing soil evidence back to a crime scene over time, bearing in mind that spatial considerations are extremely important.

This project was supported by grant numbers 2011-DN-BX-K560 and 2013-R2-CX-K010, awarded by the National Institute of Justice, Office of Justice Programs, United States Department of Justice. DNA Profiling of Soil, Soil Bacterial Profiling, Statistical Analysis

B92 Bacterial Profiling of Soil Evidentiary Items Using Next Generation Sequencing

Ellen M. Jesmok, BS, Michigan State University, 560 Baker Hall, 655 Auditorium Road, East Lansing, MI 48824; and David R. Foran, PhD, Michigan State University, Forensic Science Program, 560 Baker Hall, East Lansing, MI 48824*

After attending this presentation, attendees will understand how the bacterial composition of a soil sample can be used to link a piece of evidence to a crime scene, victim, or suspect as well as how the passage of time and storage conditions affect the bacterial community present in a soil sample.

This presentation will impact the forensic science community by elucidating the potential for bacterial profiling in tracing soil evidence back to an individual site. Next generation sequencing was used to produce ribosomal RNA (rRNA) 16S libraries that could be grouped at the taxonomic class level based on sequence differences, building a profile of each soil sample. The sequence data were statistically analyzed via a supervised classification technique, assigning evidence samples to a site of origin both through time and under different storage conditions.

Soil has generally been regarded as class evidence in forensic casework. Bacterial profiling has been proposed to help individualize soil samples and aid in tracing evidentiary items to their source location. This study tested the feasibility of connecting evidentiary bacterial profiles to specific locations over time and examined bacterial profile changes under different evidence storage conditions. The research also established whether an evidence sample originating from a specific location and habitat type can be differentiated from nearby locations having the same habitat type. A preliminary study included examination of varied evidence samples to see if bacterial profiles change over time. A shirt, sock, shoes, shovel, and tire were exposed to soil in a deciduous woodlot, then stored at room temperature for six months. Four soil samples were collected from each evidentiary item. Similar changes in bacterial class abundance and membership occurred across all evidence samples.

In the next set of experiments, eight white cotton T-shirts were rubbed in a two-foot by two-foot area of surface soil in a deciduous woodlot on day zero. Four shirts were stored at room temperature (24°C) and four at 4°C. Small (approximately 1cm²) soil-covered portions of the shirts were collected on day zero and weekly for eight weeks to characterize how soil bacterial profiles changed over time. Surface soil was also collected from the primary deciduous woodlot and eight similar woodlots biweekly to examine whether an evidentiary item can be traced back to a specific location or only classified to a general habitat type, based on statistical comparison of soil bacterial profiles.

DNA extracts were amplified using bar-coded universal 16S rRNA primers and sequenced on an Illumina® MiSeq®. To identify the bacterial classes present, 16S hypervariable regions V3 and V4 were sequenced. Bacterial libraries were filtered to remove ambiguous bases, aligned to a known bacterial sequence, and trimmed to the size necessary for analysis. Sequences were grouped at the taxonomic class level and genetic distances between the samples were calculated using the Bray-Curtis dissimilarity index. A supervised classification technique was used to create a model of the nine deciduous woodlot samples collected over time and to then predict the evidence soil samples' origins.

The soil on the evidence samples was reliably traced back to the primary woodlot immediately following collection and in the weeks following exposure, showing the utility of these methods in individualizing soil evidence. Over time, evidence sample profiles began to exhibit specific class abundance differences from the woodlot where they originated although they never became similar to the other woodlots examined. This measurable change in specific bacterial classes has the potential to act as a biological clock for how long soil has been removed from a habitat. Bacterial class abundance changes on the room-temperature T-shirts mimicked the preliminary evidentiary items study while refrigeration effectively retarded the abundance changes, maintaining similarity to the primary woodlot site. Forensically, this study shows that soil 16S rRNA next generation sequencing shows great potential for tracing soil evidence back to a specific location over time.

This project was supported by grant number 2013-R2-CX-K010, awarded by the National Institute of Justice, Office of Justice Programs, United States Department of Justice. Points of view are those of the authors and do not necessarily represent the official position or policies of the United States Department of Justice.

DNA rRNA 16S, Soil Evidence, Bacterial Profiling

B93 Quantitative Analysis of Botanical DNA by Real-Time PCR for Forensic Discrimination and Identification

*Hitomi S. Kikkawa**, 6-3-1 Kashiwanoha, Kashiwa, Chiba 277-0882, JAPAN; *Kouichiro Tsuge, PhD*, National Research Institute of Police Science, 6-3-1 Kashiwanoha, Kashiwa 277-0882, JAPAN; and *Ritsuko Sugita, PhD*, National Research Institute of Police Science, 6-3-1 Kashiwanoha, Kashiwa 277-0882, JAPAN

After attending this presentation, attendees will better understand a new highly sensitive DNA quantification method for forensically relevant botanical samples.

This presentation will impact the forensic science community by describing a more accurate and effective examination method of DNA quantification for plant specimens. The goal of this study was to develop a Real-Time quantitative Polymerase Chain Reaction (RT-qPCR) analysis for a wide range of botanical species. The amount of genomic DNA required by this method is so small that it is possible to perform more exacting examinations afterward.

Botanical evidence found at a crime scene can provide valuable information in criminal investigations; however, the specimens can be fragmentary, which prevents accurate species identification based on morphological characteristics. Therefore, DNA-based identification has begun to be introduced into botanical forensic analysis.

DNA quantification is required for accurate and effective examination. If the result of the quantitative assay is unreliable, the potential for needing to use more DNA to repeat testing to avoid failure of the analysis is likely. The loss of DNA due to the need for reanalysis affects the ability to perform further important analyses. Furthermore, with short tandem repeat profiling, a common analysis method used in forensic identification, the amount of template DNA needs to be strictly controlled.

Conventional DNA quantification methods, such as Ultraviolet (UV) -visible spectrophotometry and fluorometry, often fail to quantify a dilute DNA solution correctly because of the influence of non-specific background noise. In addition, these methods require a relatively large amount of DNA. One of the significant problems with botanical evidence is the low yield of DNA from damaged samples. In such a case, conventional methods cannot be used to quantify the sample. In contrast, qPCR requires only a small amount of DNA. This method has the ability to estimate dilute DNA solutions accurately and is well-suited for enabling plant-specific quantification.

In this experiment, primers targeting the ribulose 1,5-bisphosphate carboxylase/oxygenase large subunit (*rbcL*) gene were used in a SYBR® green qPCR analysis method. The primers utilized were selected to identify a wide range of plant species previously identified by direct sequencing of specific loci.

To test the newly developed qPCR method, *Arabidopsis thaliana* genomic DNA was extracted from leaf, stem, and root material, then the qPCR was performed on serial dilutions of the extracted DNA. The lower detection limit was 1.6pg and a straight calibration curve was obtained in the range of 1.6pg to 1ng of DNA.

To examine whether quantification by qPCR can be generally used, this method was applied to other plant species. Five families, Asteraceae, Poaceae, Cyperaceae, Rosaceae, and Ranunculaceae, which are popular plants in Japan, were selected. It was determined that all samples could be analyzed successfully using the developed qPCR method.

In conclusion, it is demonstrated that qPCR analysis is a very effective method to quantify DNA from botanical samples. Moreover, this study raised the possibility that qPCR analysis can be applied to a wide range of plant species.

B94 Variation in DNA Mixture Interpretation: Observations From NIST Interlaboratory Study Results

*Michael D. Coble, PhD**, 100 Bureau Drive, MS 8312, Gaithersburg, MD 20899-8312; and *John M. Butler, PhD, NIST, 100 Bureau Drive, MS 4701, Gaithersburg, MD 20899*

After attending this presentation, attendees will better understand the history and lessons learned from the National Institute of Standards and Technology (NIST) interlaboratory studies on mixture interpretation, including the two most recent studies, in 2005 (MIX05) and in 2013 (MIX13).

This presentation will impact the forensic science community by helping the forensic DNA community to: (1) determine the current “lay of the land” regarding Short Tandem Repeat (STR) mixture interpretation across the United States; and, (2) learn where future training and research could help improve mixture interpretation and reporting.

DNA mixtures of two or more individuals can be challenging to interpret for the forensic DNA scientist. Historically, laboratories have developed protocols to interpret mixtures based upon a combination of multiple areas of investigation including (to name a few): internal validation studies, information present in the scientific literature, training from workshops and scientific meetings, and guidelines as reported by scientific working groups such as the Scientific Working Group on DNA Analysis Methods (SWGAM) or the DNA Commission of the International Society of Forensic Genetics.

Interlaboratory studies enable examination of “big picture” views across many laboratories. In 2005 and again in 2013, interlaboratory challenge exercises were conducted by the Applied Genetics Group at NIST. The 2005 MIX05 study involved data interpretation of DNA mixtures representing four different mock sexual assault case scenarios while the 2013 MIX13 study involved data interpretation for five different case scenarios. Data from these scenarios were generated at NIST with multiple STR kits and provided to laboratories as electrophoretic data. In each MIX05 case, the “evidence” sample result, which was a mixture of genomic DNA from one “perpetrator” and one “victim,” were provided along with the single-source “victim” reference sample. All data were generated on six different STR kits (Profiler Plus[®], COfiler[®], SGM Plus[®], Identifiler[®], PowerPlex[®] 16, and PowerPlex[®] 16 BIO) from the same lot of genomic DNA mixtures. The MIX05 and MIX13 study designs and sample selection processes will be described along with a summary of results obtained from 69 laboratories with MIX05 and 108 laboratories with MIX13.

In MIX05, NIST focused on electronic data for analysis to control for the variation observed in previous studies with extraction and quantification.¹⁻³ One observation in the analysis of the results was the wide range of approaches to interpreting the same data among the different laboratories.⁴ With the publication of the 2010 SWGDAM Autosomal STR Interpretation Guidelines, many laboratories established analytical and stochastic thresholds for mixture interpretation.⁵

The MIX13 interlaboratory study was conducted to determine the current “lay of the land” in regard to STR mixture interpretation across the community. NIST also wanted to gauge the consistency in mixture interpretation across the United States after the publication of the 2010 SWGDAM guidelines. Examples of the mixture interlaboratory study will be shared along with ideas for future training and research to improve mixture interpretation and reporting in the United States.

B95 A Large-Scale DNA Mixture Interpretation Study of DNA Examiners: Inter- and Intra-Laboratory Variability

Roman Aranda IV, PhD, Defense Forensic Science Center, Office of the Chief Scientist, 4930 N 31st Street, Forest Park, GA 30297; Ivy Onyechi, MS, 5675 Princeton Oaks Drive, Sugar Hill, GA 30518; Brenda Held, 4930 N 31st Street, Forest Park, GA 30297; Karen Olson, PhD, Defense Forensic Science Center, 4930 N 31st Street, Forest Park, GA 30297; Jason J. LeBlanc, PhD, 4069 S Four Mile Run Drive, #102, Arlington, VA 22204; Henry P. Maynard III, MSFS, 390 Stovall Street, SE, Apt 3008, Atlanta, GA 30316; Blake Rowe, MS, Defense Forensic Science Center, 4930 N 31st Street, Forest Park, GA 30297; and Richard Tontarski, Jr., MFS, Defense Forensics & Biometrics Agency, 4930 N 31st Street, Forest Park, GA 30297-5205*

After attending this presentation, attendees will understand the inter- and intra-laboratory variation of genotype interpretations that occur during the DNA deconvolution process. This large-scale study attempted to quantify the variability that exists in the DNA interpretation process and was able to gather participation from a large number of DNA examiners from local, state, federal, and international forensic laboratories.

This presentation will impact the forensic science community by serving to explain the current limitations of DNA mixture interpretation, to quantify the genotype variations in the mixtures utilized in the study, and could be used to help train new DNA examiners and guide DNA interpretation protocols.

Forensic laboratories generally deconvolute DNA samples to identify DNA profiles for contributors present in the mixture sample. As the complexity of a sample increases, so does the range of genotype interpretations generated by an examiner. The interpretations may be affected by sample complexity including low template or degraded DNA, increased numbers of contributors in the sample, and the ratios and allelic overlap between each contributor in the mixture. In addition to the genotype interpretation variation generated with a given sample, various forensic laboratories utilize distinct DNA mixture interpretation guidelines and protocols that influence their interpretation of a sample. In some cases, this will determine if a sample is analyzed or deemed inconclusive; however, the degree of variation between examiners within and outside a laboratory has not been quantified.

This study attempts to quantify the variation within and between local, state, federal, and international DNA forensic laboratories using a Genotype Interpretation Metric (GIM) system developed at the Defense Forensic Science Center (DFSC). The GIM establishes a gradient to incorporate the multitude of potential genotype interpretations, converting the genotype interpretation into a quantifiable metric. Six mixtures comprised of two- or three-person contributors with varying contributor ratios were generated at DFSC using Identifiler® Plus and PowerPlex® 16 amplification kits. To establish a variation baseline, a two-person mixture was generated with a clear major and minor contributor ratio that displayed all alleles present at each locus and did not exhibit dropout at any of the loci in the electropherogram. The other five mixtures were more complex and included variations such as number of contributors, contributor ratios, and varying degrees of dropout. The resultant six mixture .fsa files were submitted to more than 275 DNA examiners at more than 50 local, state, federal, and international laboratories and the genotype interpretations were analyzed for variation at the intra- and inter-laboratory levels prior to technical review. Participants varied in their use of Combined Probability Of Inclusion/Exclusion (CPI/E), Random Match Probability (RMP), and Likelihood Ratio (LR) in their mixture interpretations; a smaller subset of examiners utilized probabilistic modeling software systems. GIM scores and an accompanying survey form were generated and analyzed for each mixture, then compared to other examiner GIM scores within and outside their laboratory. The presence or absence of genotype variation among the examiners will contribute to the overall understanding of mixture interpretation, its current limitation, and the variety of interpretational methods. The results of this study can help shed light on sources of variation seen with DNA mixture interpretation. These findings may also inform training programs for DNA examiners with the goal of reducing variation.

B96 Exploring the Impact of DNA Template Mass on the Ability to Infer the Number of Contributors Using Three Interpretation Methods

Lauren E. Alfonse, BS, Boston University School of Medicine, 72 E Concord Street, R806, Boston, MA 02118; Harish Swaminathan, Rutgers University, Center for Computational & Integrative Biology, Camden, NJ 08102; Desmond S. Lun, PhD, Rutgers University, Center for Computational & Integrative Biology, Camden, NJ 08102; Muriel Medard, ScD, Massachusetts Institute of Technology, Dept of Elec Engineering & Computer Science, 77 Massachusetts Avenue, Cambridge, MA 02139; and Catherine M. Grgicak, PhD, Boston University, School of Medicine, Biomedical Forensic Sciences, 72 E Concord Street, Rm R806D, Boston, MA 02118*

After attending this presentation, attendees will understand the impact DNA template mass has on the ability to infer the true number of contributors. This presentation will assess the accuracy of three methods: (1) Maximum Allele Count (MAC); (2) Maximum Likelihood Estimator (MLE), which is available online; and, (3) via the online tool *NOCIt*.^{1,2}

This presentation will impact the forensic science community by demonstrating that a computational tool that utilizes a continuous probabilistic approach is the preferred method by which to assess the Number Of Contributors (NOC) as it returns higher accuracy rates for low-template samples. Probabilistic approaches also provide the probability distribution over *n* contributors. This provides the user with information regarding not only the most likely number of contributors but the uncertainty associated with the measurement.

The performance of the methods was tested on single-source samples as well as two-, three-, four-, and five-person mixtures, amplified using 29 cycles, and injected for 10 seconds. Samples were amplified using 0.25, 0.125, 0.063, 0.016, and 0.008ng. MAC and MLE rely on setting an Analytical Threshold (AT) to calculate the NOC. In this study, a constant threshold of 50 Relative Fluorescence Units (RFU) was utilized. Application of MAC and MLE also uses a stutter threshold to filter out the peaks in the stutter position of allelic peaks. The stutter filter specified by the manufacturer's manual was used to filter the stutter peaks at each locus. Allele frequencies from the Caucasian population specified in the AppliedBiosystems® AmpFISTR® Identifier® Plus PCR Amplification Kit User's Manual were used to test the *NOCIt* and MLE methods.³ Unlike the MLE and MAC methods, *NOCIt* does not utilize any thresholds. Rather, it relies on a set of calibration standards to train the software and then utilizes this training set to model the baseline noise, stutter ratios, and the non-detection rates of stutter and allele peaks. Thus, 92 single-source samples were amplified utilizing the same amplification, run, and analysis protocols described above. Artifacts such as pull-up, -A, etc., were manually removed. The exported allele table was the calibration file used to train *NOCIt*.

When 75 mock-evidence samples were interpreted, preliminary results suggest that, regardless of the method, DNA template mass had a significant effect on accurately inferring the NOC to a complex stain. Both the MLE and MAC methods resulted in similar accuracy rates, which ranged from 60% to 13% for the 0.25ng to 0.008ng samples, respectively. In contrast, the accuracy rates of *NOCIt* were 87% to 27% for the 0.25ng to 0.008ng samples. MLE and MAC resulted in both overestimates and underestimates. Both methods overestimated 12% of the samples tested. These overestimations were the result of stutter peaks surpassing the stutter ratio threshold. One sample was overestimated when *NOCIt* was used to infer the NOC. Underestimations were typically due to high levels of allele drop-out and/or allele sharing between large numbers of individuals. The percentage of samples resulting in underestimations for MLE, MAC, and *NOCIt* were 43%, 52%, and 43%, respectively.

Unlike MAC, the MLE and *NOCIt* methods provide a probability distribution on the NOC. In all cases, the distribution was unimodal. Further, the uncertainty associated with the result did not change with target but instead increased with the true NOC. For example, a 1:1:2:1:1 mixture amplified using 0.125ng resulted in *NOCIt* returning two significant results: Pr(NOC=4) of 0.872 and Pr(NOC=5) of 0.128, suggesting this sample could have originated from four or five contributors. In summary, when utilizing MLE, 24% of the three-, four-, and five-person samples resulted in at least two NOCs exhibiting significant non-zero probabilities (i.e., Probability \geq 5%). When *NOCIt* was utilized, 9% of the three-, four-, and five-person samples resulted in at least two probable NOCs.

These preliminary results suggest that all methods are limited in their ability to accurately infer the NOC for samples containing low-template quantities. Though *NOCIt* outperformed the other two methods at all templates, these results suggest samples which contain at least one contributor with fewer than ten cells are prone to underestimation. Accuracy rate data from the full study that includes an additional 360 samples will be presented. Data will also be provided regarding the minimum number of calibration samples needed to train *NOCIt*.

Number of Contributors, Complex DNA Interpretation, Low-Template DNA

B97 Identification of Contributors in Complex DNA Mixtures Utilizing High-Density SNP Arrays: Influence of Sample Ancestry, Ancestry SNPs, and Reference Population

Brittin McMahon, MS, The Center for Advanced Forensic DNA Analysis, 2305 Executive Circle, Greenville, NC 27834; Thomas J. Cavanagh, MS, The Center for Advanced Forensic DNA Analysis, 2305 Executive Circle, Greenville, NC 27834; Mary L. Clair, BS, The Center for Advanced Forensic DNA Analysis, 2305 Executive Circle, Greenville, NC 27834; Jodi R. Bailey, MS, 2305-102 Executive Circle, Greenville, NC 27834; Lucy A. Davis, BHS, The Center for Advanced Forensic DNA Analysis, 2305-102 Executive Circle, Greenville, NC 27834; Christiana H. Shoopman, BA, 2305 Executive Circle, Greenville, NC 27834; and Sandra L. Close, PhD, The Center for Advanced Forensic DNA Analysis, 2305 Executive Circle, Greenville, NC 27834*

After attending this presentation, attendees will better understand the utilization of Single Nucleotide Polymorphism (SNP) genotyping to identify individual contributors to a complex mixture DNA sample and the effect of contributor ancestry, SNPs utilized during analyses, and reference population selection upon results interpretation.

This presentation will impact the forensic science community by demonstrating a practical alternative to Short Tandem Repeat (STR) analysis using capillary electrophoresis for evaluating mixed DNA samples and will also present the factors which could affect evaluation, such as reference population and ancestry of the contributor(s).

An increasing number of samples evaluated by forensic laboratories include DNA from multiple contributors, such as those routinely observed in sexual assaults and touch DNA. Advances in genotyping methodologies, routinely employed by clinical and research laboratories, provide alternatives to the use of capillary electrophoresis and STR testing. In a single assay, high density SNP Arrays can generate data from thousands to millions of genetic markers including ancestry, phenotype, X, Y, mitochondrial, and identity markers. This substantial increase in genetic data may be expected to improve the power with which contributors to a DNA mixture may be identified.

The use of SNPs to determine inclusion or exclusion of a contributor to a mixture involves comparison of the mixture with a reference population. Studies were conducted to evaluate the impact of sample ancestry, ancestry alleles used in the analyses, reference population selection on the determination of inclusion or exclusion, and on the statistics supporting the identification of contributors in sample sets utilizing the QSNP Informatics Software™. This software employs forensically relevant algorithms utilizing genetic markers to estimate the genetic distance between a sample of interest, an evidence sample, and a reference population as proposed in Homer.¹

Two methods were utilized to generate multiple reference populations: Experimental and Bioinformatic. In the Experimental method, reference populations were created by analyzing human Coriell ancestry panel samples with the Illumina® Infinium® Assay and HumanOmniExpressExome-8 BeadChip array. Allele frequencies were developed from the cumulative results of approximately 100 genomes per Coriell ancestry panel samples (AA48 and Cau50). The Bioinformatics Methodology utilized publicly available data from the 1,000 Genomes Project (<http://www.1000genomes.org>). SNPs identified by the 1,000 Genomes Project were filtered to include only those also found on the Exome8 array. Frequencies of SNPs from approximately 1,500 samples from the African and European Ancestries (AFR and EUR) were utilized for comparative purposes.

Four reference populations were compared for their impact on calculated Distance (D) and T-statistic (T) values in matched and mismatched samples of Caucasian and African ancestry. Pairwise comparisons of a matching Caucasian DNA sample (Table 1) show that D and T values are positive, indicating a match. The values for matching Caucasian samples are numerically higher when calculated against reference populations of African ancestry than when calculated against European reference populations. The Bioinformatics-derived reference populations generally provide more positive values than their corresponding experimental reference populations.

Table 1. Summary Statistics for Matched and Mismatched Caucasian Samples

	AA48		Cau50		Pooled AA48 & Cau50		AFR		EUR		Pooled AFR & EUR	
	D	T	D	T	D	T	D	T	D	T	D	T
Mean

B98 The Validation of a Statistical Tool for the Analysis of DNA Mixtures

*Dustin Foley, MS**, 1885 Old Spanish Trail, Houston, TX 77054; *Michael A. Donley, MS*, 1885 Old Spanish Trail, Houston, TX 77054; *Mark Powell, MS*, 1885 Old Spanish Trail, Houston, TX 77054; *Rebecca S. Mikulasovich, MS*, 1885 Old Spanish Trail, Houston, TX 77054; *Katherine Welch, MSFS*, Harris County IFS, 1885 Old Spanish Trail, Houston, TX 77054; and *Roger Kahn, PhD*, Harris County Institute of Forensic Science, 1885 Old Spanish Trail, Houston, TX 77054

After attending this presentation, attendees will understand a method for the validation of a statistical tool for the probabilistic genotyping of the results of analysis of forensic DNA mixtures.

This presentation will impact the forensic science community by serving as a guideline to describe how laboratories can incorporate probabilistic genotyping into protocols for DNA interpretation of mixtures.

Improvements in time of analysis, sensitivity, and cost result in it not being uncommon to encounter touch DNA samples in the crime lab. The DNA profiles obtained from touch samples are often low-level complex mixtures that are not easily or consistently interpretable using traditional mixture interpretation approaches and statistics. New methods are increasingly available that are better suited for such data.

The Harris County Institute of Forensic Sciences (HCIFS) chose the R-based statistical software package Forensim and validated its use on complex mixtures. Forensim was appealing as it is open source and available at no cost. The Forensim module of interest to HCIFS is LRmix which follows the method developed by Gill.¹ It enables the calculation of likelihood ratios for genotypes derived from complex Short Tandem Repeat (STR) profiles. The system considers allele drop-in, drop-out, and multiple contributors utilizing a semi-continuous approach that does not include peak height.

Initial validation work focused on the calculation of the probability of drop-out and drop-in, values entered manually into the LRmix module before use. The probability of drop-out value of 0.14 was determined using the counting method, the tailed method, and logistic regression for validation samples of varying concentration. The probability of drop-in was determined to be <0.01 by reviewing hundreds of casework negative controls in search of spurious allele peaks below analytical threshold but above instrument baseline. The value was set to 0.01 as that is lowest probability of drop-in LRmix will accept. LRmix module also includes a Monte Carlo probability of drop-out simulator that is run after a profile is evaluated and an assumption of the number of contributors is made. This simulation was run throughout the validation work. The calculated probability of drop-out was found to be within the simulated range reinforcing the appropriateness of the calculated probability. These simulations will also be included in casework done with LRmix.

Forty two-person and three-person complex mixtures were created from known contributors and evaluated using LRmix to demonstrate sensitivity, reproducibility, and precision. All true contributors to the mixtures were correctly associated. The likelihood ratios obtained from these samples ranged from 1×10^5 to 1×10^7 . Over 100 single-source profiles were created from randomly chosen alleles and all were correctly excluded when evaluated against the mixtures. LRmix is also capable of automating this step using the performance check module. The likelihood ratios obtained from these samples ranged from 1×10^{-55} to 1×10^{-7} . Random profiles are created based on the population database used and compared to the mixture profile. The user chooses how many profiles to compare.

Overall, the validation of LRmix demonstrates it is an acceptable method for the calculation of the likelihood ratios for complex two- and three-person mixtures and it is an economical tool that can be incorporated by a laboratory.

Probabilistic Genotyping, LRmix, Validation

B99 Development of a Pre-Screening qPCR Mixture Detection Assay Using High-Resolution Melting Curve Analysis of the Short Tandem Repeat (STR) Loci D5S818 and D18S51

Kristiana M. Kuehnert, BS, 3911 Grovewood Way, Apt L, Williamsburg, VA 23188; Nooli Hong, 1015 Floyd Avenue, Richmond, VA 23284; Sarah J. Seashols, PhD, Virginia Commonwealth University, Dept of Forensic Science, PO Box 843079, Richmond, VA 23284-3079; Todd W. Bille, MS, Bureau of ATFE, National Laboratory Center, 6000 Ammendale Road, Ammendale, MD 20705; Steven Weitz, MS, 6000 Ammendale Road, Beltsville, MD 20705; and Tracey Dawson Cruz, PhD, Virginia Commonwealth University, 1015 Floyd Avenue, PO Box 843079, Richmond, VA 23284*

After attending this presentation, attendees will have a better understanding of how a quantitative Polymerase Chain Reaction (qPCR) mixture detection assay can be used to screen low-level touch DNA samples.

This presentation will impact the forensic science community by demonstrating a way to potentially detect the presence of a mixture earlier in the DNA laboratory workflow process.

With the current forensic DNA laboratory workflow process, it is not possible to determine if a sample is a mixture of multiple contributors until after the capillary electrophoresis step has been performed and the analysis of the DNA profile shows the presence of three or more peaks at two or more loci; however, because of the large number of low-level or “touch” DNA mixture samples that forensic laboratories are receiving as evidence today, mixture detection at an earlier step in the DNA workflow process could be a beneficial tool. Receiving this information earlier would allow the analyst to determine if consumption of the sample is warranted or if protocols should be adjusted to allow for the combining of swabs from different areas of the evidence item prior to STR amplification. The quantitation step is the most logical place to add a mixture screening assay as it is a necessary and required step of the DNA analysis process, uses qPCR which can accommodate multiplexing a mixture detection assay, and because it is early enough in the workflow that changes can be made prior to downstream STR analysis.

STR loci D5S818 and D18S51 were chosen as the targets for a mixture detection assay because they are small in size and they are polymorphic enough to be able to readily determine the presence of a mixture. Fluorescent detection of the STR alleles by qPCR is most easily achieved with the use of an intercalating dye and melt curve analysis; the temperature of the STR melt product will be proportional to the number of polymorphic repeats (length) of the STR allele; however, prior to incorporation of the the STR amplification and detection in the quantitation reaction, it was important to demonstrate that the addition of an intercalating dye does not affect the performance of the quantitation kit. Thus, samples were run with and without the addition of SYTO-64[®] dye on a qPCR platform using a common commercially available human quantitation kit. Data from this study showed that the addition of an intercalating dye does not change the standard curve quality parameters or the quantitation values of unknown samples. Further, all replicates (with and without additional dye) provided values that were well within the normal inter-run reproducibility range (0.0001 to 3.3107). Next, D5S818 STR primers were used to successfully amplify and fluorescently detect standard melt products from both single-source and two-person mixture samples on the same qPCR platform using the same intercalating dye. Three distinct melting curve patterns were identified for the observed genotypes at the D5S818 locus, which was consistent with published studies. A comparison of the melting temperatures for the samples showed that the mixture samples produced melt products from 73.85°C to 74.02°C while the single-source melting curve groups ranged from 73.84°C to 73.95°C. Because there is some overlap between melting temperatures of single-source samples and mixtures, melting temperature alone cannot be used to distinguish between single-source samples and mixtures. Further mixture analysis showed that curve morphologies for the single-source and mixture samples were also very similar; however, it was noted that there was a distinct difference between the peak heights of the shoulder peaks, suggesting that this method could be used to distinguish a mixture from a single-source sample using the D5S818 locus. In order to improve resolution and magnify any melt curve differences between genotypes in future studies, High Resolution Melt (HRM) curve analysis may be more beneficial. Unfortunately, HRM in the available qPCR instrument has a fixed wavelength in the green channel which overlaps with the target fluorophores used in the quantitation kit. Thus, melt curve data from the quantitation experiments with only the intercalating dye added were reexamined. Data from these runs showed there were no melt products detectable after the quantitation amplification reaction. Consequently, it appears that the scorpion molecule used for fluorescent detection of the human quant target prevents the absorption of the intercalating dye. Therefore, high-resolution melt curve analysis, rather than standard melt curve analysis, will be possible. Future experiments will

Criminalistics Section - 2015

include demonstrating the ability to detect all common alleles at the D5S818 and D5S818 loci using high-resolution melt curve analysis on the qPCR platform and EvaGreen® as the intercalating dye for both single-source and mixed samples. To date, data show that HRM analysis of highly polymorphic STR loci during the quantitation step may be a viable method for identification of a mixture prior to STR amplification.

Mixture Detection Assay, qPCR, Quantiplex

B100 Defining the Limits of Forensic DNA Profile Interpretation: An Assessment of the Information Content Inherent in Complex Mixtures

Clare Marsden, PhD, University of California, Los Angeles, Dept of Ecology and Evolutionary Biology, Los Angeles, CA 90095-1606; Norah Rudin, PhD, 650 Castro Street, Ste 120-404, Mountain View, CA 94041; Keith Inman, MS, Dept of Criminal Justice Admin, 4068 Meiklejohn Hall, 25800 Carlos Bee Boulevard, Hayward, CA 94542; and Kirk Lohmueller, PhD, Department of Integrative Biology, 3060 Valley Life Sciences, Bldg 3140, Berkeley, CA 94720*

After attending this presentation, attendees will gain a clearer understanding of the information content in complex forensic DNA profiles. Attendees will learn to support a decision to interpret or not interpret a sample and will be able to base their decision on whether the profile supports a clear separation between a true contributor and a non-contributor.

This presentation will impact the forensic science community by providing more accurate information about forensic DNA profiles that may reliably be interpreted and those that should not be interpreted. This will provide useful information to the legal and judicial system as well as assisting laboratories in efficiently allocating resources and communicating results to their clients.

With the increasing sensitivity of DNA typing methodologies and the increasing awareness by law enforcement of the perceived capabilities of DNA typing, complex mixtures consisting of DNA from two or more contributors are increasingly being encountered; however, it remains to be shown whether it is possible to distinguish a true contributor from a non-contributor in these complex samples. In order to assess this, sets of six Caucasian genotype profiles were simulated and used to create mixtures containing two to five contributors. Each experiment was run 10,000 times. This simulation experiment was intended to illustrate the best-case scenario in which all alleles from the true contributors were detected in the simulated evidence samples. Therefore, the possibility of drop-out was not modeled for this experiment. The computer program DNAMIX was then used to compute Likelihood Ratios (LRs) for both True Contributors (TC) and Known Non-Contributors (KNC), assuming varying numbers of unknown individuals in the mixtures. These complex mixture simulations show that, even when all alleles are detected (no drop-out), true contributors can generate LRs less than one across a 15-locus profile; however, this outcome was rare (seven of 14,000 replicates (0.05%)) and associated only with mixtures comprising five contributors in which the numerator hypothesis includes one or more unknown contributors. For KNCs, LRs were found to be greater than one in a small number of replicates (75 of 14,000 replicates (0.4%)). These replicates were limited to four- and five-person mixtures with one or more unknown in the numerator. Only five of these 75 replicates yielded a LR greater than 1,000.

The informative metric for LRs is not the absolute value, but rather the separation between TCs and KNCs. By plotting the distribution of LRs, it can be seen that the ability to distinguish TCs from KNCs in mixtures containing up to five contributors is remarkably good. This is true even when multiple unknown contributors are required. Overall, these results imply that the strength of evidence that can be derived from complex mixtures containing up to five contributors, under a scenario in which no drop-out is required to explain any of the contributors, is remarkably high. Therefore, such mixtures are worth the time and effort required to perform the statistical analysis required to estimate the weight of evidence.

Mixture Interpretation, Complex Mixture, Likelihood Ratio

B101 Contributions of Physical Evidence in Human Identifications

Sandra Koch, MS, Penn State University, Dept of Anthropology, 409 Carpenter Bldg, Rm 403C, University Park, PA 16802*

The goal of this presentation will be to focus on the uses of trace evidence, specifically hairs, fibers, and fabric damage, which can aid in the identification of an individual. After attending this presentation, attendees will have a better understanding of the types of evidence criminalists examine and the potential for collaboration between forensic microscopists, forensic biologists, and forensic anthropologists.

This presentation will impact the forensic science community by showing how trace evidence can provide significant contributions in human identification analyses through the examination of physical evidence and collaboration with other specialists.

Microscopical analysis of hairs can provide information on ancestry, cosmetic treatments, and aid in identification through comparison with a known hair sample to potentially include an individual as the possible source of a hair sample. In addition to comparing hairs to a known sample and being a source of mitochondrial DNA, identification of dyes or other artificial treatments found in hair samples can corroborate information about a victim. A microscopic analysis of hair morphology and pigmentation patterns can provide information on ancestry and corroborate skeletal analysis of mixed ancestry. Artifacts of decomposition on hairs, either through postmortem root banding or fungal tunneling along the hair shaft, can provide information which, along with accumulated degree day calculations, may provide probative evidence in a criminal case.

Fibers are another source of physical evidence that can provide significant links in human identification cases. Samples of alternate knowns of the clothing worn by a victim have been used as evidence to prove contact with a suspect or scene when a body has not yet been recovered. Analysis of fabric condition and style may provide information about an individual's size, age, possible ethnicity or group affiliation, and trauma. Fabric damage in conjunction with an anthropological analysis of skeletal remains have been able to indicate a type of weapon, its general dimensions, and the number of injuries in an area covered by clothing. The degree of degradation for clothing depends on the type of fiber(s) that a garment is composed of, the fabric construction, and the environment from which the clothing is recovered.

Including a forensic examiner qualified in hair and fiber examinations to human identification investigations can contribute an area of expertise that can greatly assist in providing information on ancestry, decomposition, trauma analysis, and corroboration of victim identity.

Criminalistics, Trace Evidence, Anthropology

B102 Pollen Evidence of Diet and Environment From a Nebraska Mummy

Marina Milanello do Amaral, MS, Instituto de Criminalística, Superintendência de Polícia Técnico-Científica, 233 Jovina de Carvalho Dau, Taboão da Serra 68583, BRAZIL; Nicole A. Wall, MFS, University of Nebraska-Lincoln, School of Natural Resources, 804 Hardin Hall, Lincoln, NE 68583; and Karl J. Reinhard, PhD, School of Natural Resources, 719 Hardin Hall, Lincoln, NE 68583-0987*

After attending this presentation, attendees will understand how pollen and microfossil evidence can be recovered from a mummy. Attendees will learn how control samples can be used to sort out contamination of internal mummy contents through quantification and statistical analysis.

This presentation will impact the forensic science community by showing how the attention to quantification of pollen remains can provide a foundation for understanding the influence of ambient pollen contamination in recovery of pollen during the autopsy process. In this way, victim diet and activities within a region is able to be discerned.

Palynological investigation of archaeological mummies established methods of environmental and dietary study.^{1,2} These methods have been applied to mummies in criminal and Missing in Action (MIA) situations.

The case of a mummified homicide victim in Nebraska provided an opportunity to apply these methods to actual forensic material. The individual was thoroughly desiccated in such a manner that the thorax was essentially hollow. Control samples from the area in which the corpse was located provided an idea of the normal ambient pollen of the crime scene. Samples from the victim's sacrum as well as a section of intestine were analyzed. Another internal control sample of powder was recovered from the area inferior to the diaphragm. Finally, pollen was washed from the victim's hair. A section of intestine was rehydrated and microfossils were recovered from the inside of the section.

Quantification was based on the Lycopodium method based on adding a known number of spores to a known amount of sample.¹ The number of pollen grains per gram ranged from 980 to 1,680. This provided a quantitative basis for analysis.

The control samples were dominated by wind-pollinated, environmental types. The internal intestine sample was dominated by dietary pollen. The sacrum sample was also dominated by dietary types, with some environmental types. The internal powder of the corpse exhibited a dominance of environmental types which suggests that contaminant pollen entered the corpse at the time of autopsy. It is suspected that the vibration of the Stryker autopsy saw caused some external pollen grains to fall into the corpse. The intestinal section method, proven important in archaeological investigations of mummies, can be directly transferred to forensic investigations.

Pollen consistent with the genus Brassica (broccoli type) was most common with 980 grains per milliliter of the final material recovered from the sample. Traces of oak, hackberry, and clover were present. Pollen was more abundant in the sacrum sample. Brassica-type was most common and approximately 1,680 pollen grains were present per gram. Other dietary types included maize (200 grains per gram) and prickly pear cactus (80 grains per gram). A variety of environmental types including goosefoot, ragweed, juniper, dandelion, grass, pine, cottonwood, oak, and cattail were also encountered. All of these types grew in the vicinity of the victim's house.

The powder from the diaphragm area contained only air-borne ambient pollen consistent with the pollen from control samples. The victim lay on a rug which was heavily contaminated by air-borne pollen leading to the transfer of pollen from the rug to the victim's chest and abdomen. This transfer provided a source of contaminant pollen which apparently entered the hollow thorax during the autopsy, probably related to the vibration of a Stryker autopsy saw.

A second case involved an analysis to help determine the identity of an MIA case from the Korean War. The goal of this analysis was to determine the decedent's diet to assess his military identity. The analysis of a coprolite recovered from the individual revealed a diet completely composed of indigenous Korean plant foods. Comparison with Korean mummies that are currently under analysis in the laboratory confirmed that the MIA diet and medicine pollen is completely consistent with Korean culinary traditions that persisted for hundreds of years. The individual components of the diet are consistent with Korean food and medicinal teas. It appeared that this was the body of an indigenous individual; however, the remains were ultimately identified as those of a United States serviceman. Thus, the decedent was subsisting on indigenous foods in the days immediately before he was killed. In such cases, adaptation of military personnel to indigenous foods obscures cultural identity.

B103 Recent Applications of Stable Isotope Forensics for Tracking Region-of-Origin and Residence Patterns of Unidentified Individuals

*Eric J. Bartelink, PhD**, California State University, Chico, Dept of Anthropology, Butte 311, 400 W First Street, Chico, CA 95929-0400; *Lesley A. Chesson, MS*, IsoForensics, Inc, 421 Wakara Way, Ste 100, Salt Lake City, UT 84108; *Brett J. Tipple, PhD*, IsoForensics, Inc, 210 Wakara Way, Ste 100, Salt Lake City, UT 84108; and *Gregory E. Berg, PhD*, JPAC-Central ID Laboratory, 310 Worcester Avenue, Joint Base Pearl Harbor-Hickam, HI 96853-5530

The goal of this presentation is to highlight recent applications of stable isotope forensics for predicting region-of-origin and residence patterns in unidentified human remains. After attending this presentation, attendees will better understand the applications and limitations of stable isotope forensics as an investigative tool in human identification.

This presentation will impact the forensic science community by demonstrating how new approaches in stable isotope forensics can aid in the resolution of unidentified remains cases.

Over the past decade, the use of stable isotope analysis has become an increasingly important part of forensic casework. More recently, stable isotope analyses have been applied to unidentified human remains cases from local jurisdictions, United States service personnel from past wars and conflicts, undocumented border crossers, and victims of genocide. These applications of stable isotope forensics have been successful due to the recent development of baseline water and geological “isoscape” maps for various regions. In addition, recent collaborations between forensic anthropologists and analytical chemists have provided opportunities to develop and test new methods by evaluating samples of known origin.

Stable isotope ratios measured in human tissues, such as bones, teeth, and hair, provide a history of a person’s diet and residence patterns. Bulk stable carbon and nitrogen isotope values of bone collagen or keratin (e.g., hair, nails) provide information on the types of foods consumed during life, which in turn may reflect regional or cultural dietary patterns. Stable oxygen isotopes of tap water and precipitation water vary between regions due to environmental factors (e.g., distance from the coast, elevation, aridity) and are incorporated into teeth and bone bioapatite at the time of tissue formation. Strontium isotopes are a product of the geological age of the underlying bedrock in a region and are incorporated into local plants and the animals that consume them, including humans. Thus, stable oxygen and strontium isotopes can be used together as an effective “geolocation” tool for predicting region-of-origin or residence patterns of unidentified individuals. This multi-isotope approach provides independent lines of evidence that narrow down residence patterns and/or region-of-origin of unidentified remains from tissues that form at different intervals (e.g., tooth enamel, bone, hair), which can generate new investigative leads. The approach is most effective in cases where the decedent was born outside of the area or was a recent traveler to the area in which he/she died.

A case study from the western United States demonstrates this potential for narrowing down region-of-origin through comparison of oxygen and strontium isotopes of tooth-versus-bone bioapatite, which represent childhood and adult residence patterns, respectively. Isotopic data indicate that the decedent was not local to the area based on oxygen and strontium isotope values of tooth enamel bioapatite; however, bone bioapatite oxygen isotope values were not inconsistent with the region-of-origin and include other possible regions such as western North America.

A second case study discusses the application of stable isotope forensics for predicting region-of-origin of human bone obtained by the Joint POW/MIA Accounting Command, Central Identification Laboratory. Previous research using stable carbon isotopes of bone collagen and bioapatite found that Southeast Asians could be discriminated from United States Americans with 96.3% accuracy (cross-validated) based on cultural differences in diet (mixed C₃/C₄ diet among United States Americans versus predominately C₃ diet among Southeast Asians).¹ These samples were recovered from various sites in Southeast Asia and were selected from known incidents and were of known origin. Analysis of stable oxygen isotopes of bone bioapatite from three samples allowed for more specific region-of-origin prediction, which could be further narrowed down based on contextual information on the incidents.

The use of stable isotope analysis has enormous potential in forensic science and recent approaches have been successful in predicting probable region-of-origin and residence patterns in undocumented border crosser cases and in victims of genocide.

Forensic Anthropology, Stable Isotope Analysis, Human Identification

B104 Lessons Learned From the DNA Analysis of More Than 11,000 Skeletal Samples: More Than 20 Years of Process Improvements

Suni M. Edson, MS, Armed Forces DNA ID Lab, 115 Purple Heart Drive, Dover AFB, DE 19902; and Stephanie R. Ah Sam, MS, JPAC-CIL, 310 Worcester Avenue, Bldg 45, Joint Base Pearl Harbor-Hickam, HI 96853*

After attending this presentation, attendees will better understand how rapid adoption and implementation of new procedures within their laboratories will increase DNA reporting success rates for skeletonized remains that are more than 40 years of age.

This presentation will impact the forensic science community by providing a framework of adaptations implemented by the Armed Forces DNA Identification Laboratory (AFDIL) and the Joint POW/MIA Accounting Command Central Identification Laboratory (JPAC-CIL) that can serve as a model for any laboratory seeking to improve DNA recovery from skeletonized human remains.

Since the creation of the laboratory in 1992, the AFDIL has striven to provide world-class DNA analysis to aid the JPAC-CIL in the identification of missing United States service members. Over the past 22 years, procedures have been constantly adapted and improved in order to stay at the cutting edge of DNA technology. This presentation will show how changes to mitochondrial DNA (mtDNA) and autosomal Short Tandem Repeat (auSTR) amplification strategies, as well as DNA extraction and general laboratory protocols, have significantly increased results over time. The increase in DNA reporting success rates will be of particular use to any laboratory performing work on missing persons or cold cases due to the similarity in degradation patterns over time.

Thoughtful application of modifications to standard operating procedures can reap enormous benefits when applied within practicing laboratories. In 1999, the introduction of mini-primer sets allowed for mtDNA sequence data to be generated from previously unreportable samples due to amplicon size. In 2001, a customized LIMS was introduced, which allows for the tracking of samples from cradle (arrival) to grave (final report). Specially designed modules provide for automated comparisons of casework mtDNA profiles to thousands of family references samples in a matter of seconds, allowing analysts to spend more time in the laboratory rather than manually calculating comparisons. Introduction of capillary electrophoresis in 2002 further improved the speed by which samples could be processed within the laboratory.

While all of these previous modifications showed a positive impact on sample processing, the sampling procedure at JPAC-CIL remained essentially the same: remove a 5.0g fragment of compact bone to send to AFDIL for DNA processing of which 2.0g was needed for extraction. This technique generated successful results nearly 85% of the time, but cases that had much smaller bone fragments or fragments of poor quality were unable to be sampled. In 2007, the demineralization extraction protocol was implemented. The success rate for mtDNA processing jumped to more than 92% and the sample size for extraction was reduced ten-fold. In the years following implementation of this extraction technique, JPAC-CIL has been able to slide their sampling strategy to increasingly smaller samples. Over 24% of samples submitted currently weigh less than 2.0g. Cases that would have previously been shelved due to size of available bone fragments can now be processed with positive results. A simple improvement in the extraction procedure removed the restrictions of both sample size and quality, allowing almost any skeletal element to be sampled successfully.

In the summer of 2013, AFDIL incorporated an inorganic purification step into the extraction procedure, completely eliminating phenol, chloroform, and butanol from use. While this modification has had only a moderate impact on mtDNA reportability, autosomal success has more than doubled. AFDIL has used commercially available auSTR and Y-chromosomal Short Tandem Repeat (Y-STR) kits since 2007 to support mtDNA matches or separate individuals with common mitotypes. Both auSTR and Y-STR success rates have jumped from 25% to more than 45%, thus making the use of nuclear DNA testing on aged skeletal samples a more consistently viable option.

Progressive improvements will only provide positive results to any forensics laboratory working on missing persons or cold cases, as examination of changing mtDNA, auSTR, and YSTR success rates from more than 11,000 osseous samples demonstrates. The adaptations described above and implemented by AFDIL and JPAC-CIL serve as a model for any laboratory seeking to improve DNA recovery from skeletonized human remains, to include laboratories performing identification of Unknown Human Remains (UHR).

The opinions or assertions presented are the private views of the authors and should not be construed as official or as reflecting the views of the Department of Defense, its branches, the United States Army Medical Research and Materiel Command, the Armed Forces Medical Examiner System, or the Joint POW/MIA Accounting Command-Central Identification Laboratory.

B105 Modeling 3D Facial Appearance in Relation to Sex, Genetic Ancestry, and Individual Genes Enables Facial Prediction From DNA

Arslan Zaidi, MS, Penn State University, 409 Carpenter Bldg, University Park, PA 16802; Peter Claes, PhD, KU Lueven, Herestraat 49 - bus 7003, B-3000, Leuven, BELGIUM; and Mark D. Shriver, PhD, Penn State University, 409 Carpenter Bldg, University Park, PA 16802*

After attending this presentation, attendees will better understand the variation in 3D facial shape across the globe and how it can vary with respect to sex, genetic ancestry, and individual genes. Attendees will also have a better idea of the methodological challenges involved in predicting complex physical traits using these three variables.

This presentation will impact the forensic scientific community by introducing an approach that represents an important advance in predicting physical appearance from genetic data.

Genomic knowledge, analytical methods, and technology are approaching a stage where questions regarding the evolutionary-genetic architectures underlying variation in human physical traits can be formulated and directly addressed. The recent successes in discovering the genes and histories of skin pigmentation provide compelling examples of this approach. This presentation will review these results and discuss the fundamental considerations in Genotype-to-Phenotype (G2P) mapping especially with regard to the definition and measurement of traits and the use of admixed populations to study recently evolved traits. Using facial features an example trait, both the benefits and challenges inherent in studying phenotypes that are not only multivariate, but are owing to complex patterns of modularity are also multipartite. An approach that has been recently developed to investigate facial variation, called Bootstrapped Response-based Imputation Modeling (BRIM) will also be discussed. This presentation will demonstrate how this technique was used to model the effects of sex, ancestry, and individual genes on the face.

BRIM is unique in that it allows for the compounding of multiple independent response variables into a single scalar customized to the predictor variable of interest. By combining subjective observer assessments of the face with these methods, the capacity to both discover and model the effects of genes on facial features has been demonstrated and provides support for the hypothesis that the pressures of sexual selection shaping the human face are both substantial and dynamic and have also affected the human facial perceptual facilities. These findings will be discussed in light of forensic predictions.

Criminalistics, Molecular Photofitting, Genetics

B106 The Identification Process Involving American Citizen (AMCIT) and Undocumented Border Crossers (UBCs): The Pima County Office of the Medical Examiner (PCOME) Experience

Bruce E. Anderson, PhD, Pima County OME, Forensic Science Center, 2825 E District Street, Tucson, AZ 85714*

After attending this presentation, attendees will better understand the complexities encountered during the identification process. Additional postmortem descriptors may be necessary to complete some identifications.

This presentation will impact the forensic science community by describing how personal identification may require more than the match between a databased DNA profile or fingerprint record. Unless the true name and nationality can be deciphered, Next Of Kin (NOK) notification is usually not possible. Emerging technologies that can be utilized to extend the postmortem description beyond DNA profiles and fingerprint records can address this issue.

The PCOME is actively monitoring the case files of more than 1,000 unidentified persons dating back 50 years. The great majority of these cases have been sampled for DNA analyses, with more than 600 of these cases having already yielded complete or nearly-complete DNA profiles. Many of these profiles have been entered, or are in the process of being evaluated for entrance, into the Federal Bureau of Investigation's (FBI's) Combined DNA Index System (CODIS). Although the vast majority of these unidentified individuals are currently believed to be foreign national migrants who died while in transit from Mexico to Arizona as UBCs, their unidentified status requires the PCOME to consider each case as a potential AMCIT until identified as a foreign national. Thus, all technological tools available within the United States medicolegal sphere to assist with the identification process are utilized. In addition to CODIS, the FBI's Automated Fingerprint Identification System and National Dental Image Repository, the Department of Homeland Security's Biometric Support Center's US-VISIT and IDENT databases, the Open-GIS Mapping System, the National Missing and Unidentified Persons System, and the National Center for Missing and Exploited Children are all employed toward this end. While the PCOME actively engages in the identification process armed with DNA profiles, fingerprint records, dental records, and missing person reports, the suspected nationality status of the unidentified decedents is regularly being reviewed. Thus, any identification technology, emerging or long-established, that will assist with global region of birth or a migratory pattern is of great interest. Recent advances in technologies such as isotope ratio analysis may allow the PCOME to be more confident in the categorization of unidentified individuals as either likely UBCs or likely AMCITs. The importance of this categorization lies in the fact that a missing person's antemortem records, essential in the identification process, may be more readily located if a specific nationality is suspected or has been excluded from consideration. Examples of "identified" foreign nationals, who have matched to their own DNA profiles in CODIS but remain unidentified according to PCOME protocols because an alias name was provided to United States law enforcement, will be discussed. In these cases, the true name, nationality, and thus NOK remain unknown. This discussion should highlight the need for additional postmortem descriptors in order to achieve a more complete resolution of some unidentified cases. Innovative and emerging technologies that provide these additional descriptors hold the promise to improve the identification process by allowing for a more thorough comparison of antemortem and postmortem records.

Identification Process, Postmortem Descriptors, Emerging Technologies

B107 A Novel Software-Based Toolset for Latent Print Examination

*Donald T. Gantz, PhD**, George Mason University, Dept of Applied IT, MS 1G8, 4400 University Drive, Fairfax, VA 22030; *Daniel Gantz**, Sciometrics, 2027 N Utah Street, Arlington, VA 22207; *Mark A. Walch, MA, MPH*, Sciometrics LLC, 2303 Dulles Station Boulevard, Herndon, VA 20171; *Maria A. Roberts*, 2501 Investigation Parkway, Quantico, VA 22135; and *JoAnn Buscaglia, PhD*, FBI Laboratory, CFSRU, 2501 Investigation Parkway, Quantico, VA 22135

After attending this presentation, participants will better understand the features and benefits of using a novel automated system to augment their existing tools for latent print searching and matching.

This presentation will impact the forensic science community by reporting on the development and testing of a novel toolset for latent print examination. The toolset provides a larger candidate list with latent features mapped onto the reference print, thereby potentially increasing the likelihood of identification if the database contains the reference print. The use of this toolset has potential cost-saving benefits in reducing examiner time and increasing the efficiency of expert examiners.

This presentation will introduce innovative toolsets for latent fingerprint examination that significantly reduce the labor intensity of examination and make possible the detailed comparison of a latent print to large databases of reference prints. The toolsets result from an innovative technology that captures ridge and furrow information in a fingerprint via a concept of Ridge-Specific Markers (RSMs).¹ RSMs are exploited to produce invertible overlays between a latent and a reference print that removes the local non-linear distortion between the prints. Each overlay is scored at the pixel level by an algorithm that evaluates the accuracy of the overlay at the pixel level within ridges and furrows. The overlay technology and scoring algorithms were previously presented and the performance of the RSM technology using the National Institute of Standards and Technology (NIST) Special Database 27 latent print data set was demonstrated; this presentation reports on new results of testing the current toolset by latent print examiners within various organizations.¹⁻³

Latent prints often offer the best possibility for identification of suspects in criminal and terrorist cases; however, latent prints are also the most difficult to analyze by conventional automated methods due to poor image quality and limitations of the number of minutiae available for identification. The challenge in matching latent prints becomes one of establishing identity within the constraints of the limited information provided.

The presented toolset incorporates a unique method that establishes how well one fingerprint will overlay onto another. The overlay leads to a score that provides a quantitative assessment of the fit between prints with the objective of determining whether two fingerprints potentially came from the same finger. This method permits fingerprint matching using the rich feature set provided by the ridge structure enabling matching to take place without reliance on traditional minutiae (i.e., ridge edgings and bifurcations).

The toolset runs a latent against a reference print database, such as the prints returned from an Automated Fingerprint Identification System (AFIS) search or a set of prints of interest in a specific case. The toolset performs totally automated processing of the latent and reference images to include: (1) quality masking of the images; (2) binarization of ridges and furrows; (3) invertible non-linear overlays of the latent on each reference image; (4) pixel-based scoring of overlays to reference images based on the accuracy of the overlays; (5) automated locating and minutiae markup in the latent and all reference images; (6) visual assessment of level-3 features (when level-3 feature information is available in the images); and, (7) interactive image overlays supporting comparisons of latent and reference images that allow real-time visual assessment of corresponding locations in the latent and each reference print.

The magnitude of the score indicates the degree of similarity between the latent and the reference image. Scores are pixel-based for pixels along the one-pixel-wide centerline of both ridges and furrows; that is, scoring is an aggregate of the similarity of a latent and a reference print on the totality of ridges and furrows within an examiner's region of interest as marked on the latent print.

This presentation will also showcase the listed functionalities through a live demonstration of the toolset, specific to latents and reference print databases. Through this presentation, latent print examiners will become aware of enhancements to latent print examination through the RSM technology that potentially reduce examiners' labor and permit a broader quality range of latent prints to be exploited.

B108 Fingerprint Identification and Error-Rate Estimation Based on the Congruent Matching Cell (CMC) Method

*Wei Chu**, 100 Bureau Drive, Mail Stop 8212, Gaithersburg, MD 20899; *Junfeng J. Song*, MS, 100 Bureau Drive, Mail Stop 8212, Gaithersburg, MD 20899; *Melissa K. Taylor*, BA, 100 Bureau Drive, Gaithersburg, MD 20899; *Robert M. Thompson*, BS, NIST, Office of Special Programs-Forensic Sciences, 100 Bureau Drive, Mail Stop 8102, Gaithersburg, MD 20899; and *Johannes A. Soons*, PhD, NIST, 100 Bureau Drive, Mail Stop 8223, Gaithersburg, MD 20899

After attending this presentation, attendees will learn how to discriminate between matching and non-matching fingerprint image pairs by determining congruency of cell pairs divided from the original fingerprint image pair, as well as the error-rate estimation procedure.

This presentation will impact the forensic science community by providing fundamental scientific and statistical support to fingerprint identification.

The CMC method is an approach originally developed at the National Institute of Standards and Technology (NIST) for the accurate forensic identification of firearm tool marks. The CMC method is applied in fingerprint identification, aiding in the evaluation of the strength of fingerprint evidence by providing a technique to determine the random match probability of fingerprint evidence as well as the probability of false positives and negatives. In this presentation, promising initial results on the application of the CMC method to fingerprint identification are described.

The CMC method for comparing two samples is based on the correlation of pairs of small cells instead of the entire sample. Two sets of cells are a congruent matching pair if they have a high degree of similarity, typically expressed by the maximum value of the area Cross-Correlation Function (CCF_{\max}) and if their registration position and orientation are consistent with those of other congruent cells. Thus there are three sets of parameters identifying cell pairs originating from the same source: (1) the CCF_{\max} value; (2) registration position x and y ; and, (3) registration angle θ , with associated thresholds T_{CCF} , T_x , T_y , and T_θ . An identification requires a certain minimum number of CMCs. It was observed that the correlation of cells instead of the entire surface yields a good statistical separation between the number of CMCs for matching and non-matching samples, even if major sample areas have missing features. The CMC method also enables an approach to estimating error rates. The combined false positive and false negative identification probability for each correlated cell pair, P_1 and P_2 , can be estimated from the statistical distributions of the three sets of identification parameters and their thresholds. These probabilities are then used to estimate the probability of a false exclusion or false identification for a given number of compared cells and observed CMCs.

After modifications, the CMC method was applied to fingerprint identification. Forty-four fingerprint images randomly selected from the NIST fingerprint (10-print) database were compared. Each fingerprint image was divided into a cell array with an average of 225 cells. The number of CMCs for the 924 Known Non-Matching (KNM) fingerprint pairs were distributed in a range from 0 to 5. The number of CMCs for the 22 Known Matching (KM) fingerprint pairs were distributed in a range from 8 to 60. The initial results show significant separation between the KM and KNM CMC distributions and no false identifications or false exclusions were made. This study hopes to obtain a wider separation after tailoring the registration algorithms and CMC criteria to fingerprint patterns. Error-rate estimation will require tests on larger and more varied fingerprint sets to estimate typical "local" cell-matching probabilities in the patterns for images of various quality levels. It avoids errors introduced by incorrect feature identification, which lowers identification accuracy when comparing imperfect fingerprint images.

Fingerprint Identification, Error Rate, Congruent Matching Cells

Criminalistics Section - 2015

B109 Development of Fingerprints From Items Submerged in Fresh Water Over Time

*Pamela Class**, Arcadia University, 450 S Easton Road, Glenside, PA 19038; *Kimberlee S. Moran, MSc*, Center for Forensic Science Research & Education, 2300 Stratford Avenue, Willow Grove, PA 19090; *Heather E. Mazzanti, MSFS*, 450 S Easton Road, Glenside, PA 19038; and *Elana Conant, MS*, Cedar Crest College, 100 College Drive, Miller #10, Allentown, PA 18104

After attending this presentation, attendees will better understand which fingerprint development and analysis techniques to use in cases involving items submerged in different bodies of fresh water.

This presentation will impact the forensic science community by raising awareness of the fact that little research has been conducted on developing fingerprints from items that have been submerged in water environments. Previous research on obtaining fingerprints from submerged items has been performed in a laboratory setting using deionized water. Since deionized water is not commonly found outside a laboratory setting, the results from the previous study are not beneficial for possible crime scene settings. It is expected that the results from previous studies will vary from the results of this study. Unpublished research has been performed on developing fingerprints from items submerged in saltwater environments.

In this study, a variety of types of items were placed in three different fresh water environments: a tub filled with tap water, a chlorinated pool, and a lake. Items that were placed in the pool and lake setting were placed in a mesh laundry bag for ease of recovery. The items that were examined included glass bottles, plastic bottles, copper piping, stainless steel piping, PVC piping, duct tape, and plastic bags. These items were selected because they are non-porous and are frequently found as items of evidence. Two different types of metal piping were selected to show that different metals produce different results in the same environments. Non-porous items were selected because the methods used for development work best on these types of items. Two sets of items were set up for each day. A depletion series of five thumbprints from the primary investigator's right hand was placed on each item. The items were then submerged in one of the three different environments, and removed in 24-hour increments. The first set was developed using Small Particle Reagent (SPR) and the second set was allowed to dry. After the items were dried, they were developed using cyanoacrylate fuming. The cyanoacrylate fuming was performed at the Montgomery County District Attorney's office in Norristown, PA. Based on this research, fingerprints containing level 2 detail can be developed from items submerged in fresh water for multiple days using SPR and cyanoacrylate fuming, meaning that investigators should attempt recovery of fingerprints from items even though the item has been submerged in a fresh water environment.

Fingerprints, Submerged Items, Small Particle Reagent (SPR)

B110 DNA Profile From a Fingerprint Developed With a Columnar Thin Film

Stephanie Plazibat, BA, 107 Whitmore Laboratory, University Park, PA 16802; Zachary C. Goecker, BS, 14197 Ten Acres Court, Saratoga, CA 95070; Stephen Swiontek, Pennsylvania State University, 212 EES Bldg, University Park, PA 16802; Akhlesh Lakhtakia, PhD, DSc, 212 EES Bldg, University Park, PA 16802; and Reena Roy, PhD, Pennsylvania State University, Forensic Science Program, 325 Whitmore Lab, University Park, PA 16802*

After attending this presentation, attendees will understand that an emerging fingerprint-development technique preserves DNA from body fluids on a fingerprint and that good quality DNA profiles can be obtained from the fingerprint. It is hypothesized that the developed body-fluid fingerprints will be of better quality than those that have not been developed and that the fingerprints will give the same quality DNA profiles.

This presentation will impact the forensic science community by promoting knowledge of the options available to forensic scientists in developing body-fluid fingerprints. Moreover, this presentation describes how to obtain DNA from fingerprints and subjectively and objectively grade the quality of those fingerprints. The Columnar Thin Film (CTF) method is also analyzed in regard to fingerprint quality and the potential for DNA preservation.

DNA and fingerprint analyses are the two major methods of identification used in forensic science. If these two methods can be implemented on the same sample, identification of a suspect or a victim can be greatly improved. In this research, blood was collected by pricking the finger and smearing it on the fingertip. Saliva was collected by dipping fingers into saliva. Sixty fingerprints produced with blood and 40 fingerprints made with saliva (100 total fingerprints) were placed on brass. Fingerprints were allowed to dry at room temperature and CTF deposition occurred the following day. Half the fingerprints were developed with CTF technique and the other 50 remained undeveloped.

The CTF technique involves the resistive heating of a material, which sublimates and condenses conformally as a tight stack of upright nanoscale columns atop a fingerprint. The CTF entombs the entirety of the residue, serving as a barrier between the residue and the environment, and potentially preserving DNA in the residue.

After the fingerprints were developed, the substrate was swabbed to collect the residue comprising the fingerprint emulsion, the body fluid, if necessary, and the CTF. All samples underwent DNA analysis. In the case of the fingerprints with body fluids, the DNA was extracted from the collected residue and quantitated using Real-Time Polymerase Chain Reaction (PCR) technology. Concentration of DNA ranged from 0.226ng/ μ L to 7.05ng/ μ L. Approximately 1.0ng of DNA was amplified with the Identifiler® Plus amplification kit for all fingerprint samples. DNA from the amplified product was detected by capillary electrophoresis injection on the Applied Biosystems® 3130xl Genetic Analyzer. The generated data was analyzed using GeneMarker® HID Software from SoftGenetics®.

Latent fingerprints without body fluids were also harvested and placed on glass. With these latent fingerprints, the extraction procedure involved low-template DNA-analysis methods previously used in this study's laboratory. DNA was quantified using the Trio kit from Applied Biosystems® and the InnoQuant™ kit from InnoGenomics. The yield of DNA from fingerprints, which had been aged for defined periods of time, allowed the researchers to compare the degree of degradation which took place between the enhancement techniques.

This research indicates that fingerprints wetted with body fluids and developed with the CTF technique are better quality than latent fingerprints. It was possible to generate complete DNA profiles from 100% of the fingerprints wetted with body fluids and developed by the CTF technique. The profiles were concordant with the reference samples of the donors. Of the fingerprints wetted with body fluids and not developed by the CTF technique, complete profiles were obtained from 83.33% of the samples, partial profiles were generated from 8.33% of the samples, and no profile was obtained from 8.33% of the samples. Since a measurable amount of DNA and complete DNA profiles were obtained from these fingerprints after CTF exposure, it was determined that the CTF had no negative effect on the methods of DNA analysis, and therefore it is believed that the DNA profiles obtained from CTF-developed fingerprints are of the same quality as non-developed fingerprints. This research also indicates that there is a sufficient quantity of DNA in multiple latent fingerprints to analyze DNA amplicon length ratios. Thus, it is possible to determine the amount of degradation in the sample. Overall, the combination of the CTF-development technique and DNA analysis could prove useful for identification purposes in a crime laboratory.

Fingerprints, DNA, Columnar Thin Film

B111 Mobility Empowered and Sustainable AFIS (MESA)

Mark A. Walch, MA, MPH, Gannon Technologies/Sciometrics, 2303 Dulles Station Boulevard, Ste 105, Herndon, VA 20717; Donald T. Gantz, PhD, George Mason University, Dept of Applied IT, MS 1G8, 4400 University Drive, Fairfax, VA 22030; and Daniel Gantz, Sciometrics, 2027 N Utah Street, Arlington, VA 22207*

After attending this presentation, participants will better understand the capabilities as well as the possibilities of off-the-shelf smartphone technology as a fingerprint-capture device in support of identity matching.

This presentation will impact the forensic science community by reporting on the development and testing of a novel approach called MESA (Mobility Empowered and Sustainable AFIS (Automated Fingerprint Identification System)) technology for using the forward camera on a conventional smartphone as a fingerprint-capture device. No additional sensors are used on the device. MESA represents a software-only solution and the use of this technology will greatly broaden the availability of fingerprint data for law enforcement, intelligence, and defense purposes.

This presentation will introduce MESA as a means of capturing useful fingerprint information through conventional smartphones. Smartphones are ubiquitous devices with very powerful sensor capabilities. The typical smartphone has an eight-megapixel camera which offers the opportunity for high-resolution photography of fingers and hands suitable for biometric identity matching. Fingerprints are truly the “human barcode” and among the best measures of human identity available. Fingerprints are similar to DNA as biometric identifiers because they can be obtained either directly from individuals or from items that individuals have touched or places they have been. An additional advantage of fingerprints is they are readily captured through well-proven techniques; however, “traditional” fingerprints represent only a portion of what the hand offers in terms of identity. Other data available takes the form of “palmprints” which is a class that includes not only the palm but also includes the second and third joints of the fingers and the finger sides and tips. Because the focus of current fingerprint-capture technology is on fingers, the palm class of prints is often ignored. In fact, most portable scanners have no palm capability — but smartphones, through their high-resolution cameras, do have the capability of capturing images from the palms as well as the fingers.

Underlying MESA is an innovative method for matching latent fingerprint fragments only a few millimeters in diameter. The method is based on the ridge-specific marker technology that employs a unique algorithm that establishes how well one fingerprint will overlay another and can be used for matching as well as comparing multiple images from the same finger to obtain the best composite result. This method is important when dealing with fingerprint photographs from smartphones since there are many factors — focus, movement, and image occlusion due to lighting — that can cause difficulty during the matching process.

The discussion will address the issue of standards as they relate to fingerprints generated from photographic images and touch on the issue of fingerprints as “big data” given the opportunity to expand collection. Finally, the presentation will showcase the power of smartphone fingerprint capture through a live demonstration of a fingerprint captured in real time and matched against a laptop-based AFIS. Through this presentation, all practitioners who work with fingerprints as an identification tool will become aware of how a widely used tool can become a critical asset in the identification process.

Fingerprint, Mobile, AFIS

B112 Bloodstain Patterns Associated With Gunshot Wounds — Misconceptions

Peter R. De Forest, DCrim, PO Box 141, Ardsley, NY 10502; Peter A. Pizzola, PhD, Peter A. Pizzola, Inc, PO Box 41, Yonkers, NY 10704; Ralph R. Ristenbatt III, MS, Penn State University, Forensic Science Program, 107 Whitmore Laboratory, University Park, PA 16802; and Peter J. Diaczuk, BS, 445 W 59th Street, New York, NY 10019-2925*

The goal of this presentation is to provide attendees with a better understanding of the conditions under which gunshot wounds will produce blood droplet spatter.

This presentation will impact the forensic science community by having a positive impact on bloodstain pattern interpretation in shooting cases by clearing up misconceptions.

Much confusion appears to exist concerning bloodstain patterns produced by gunshots. This confusion can lead to misinterpretations in attempts to reconstruct past shooting events transpiring at crime scenes. Confusion on the part of laypersons such as lawyers, judges, or the members of a jury may be at least partially attributable to graphic media portrayals of shootings in film and television where volumes of blood spurt out of the wounds. If transcripts of testimony and textbooks are a good indication, confusion also exists among some experts charged with the responsibility of reconstructing shootings. The latter may be attributable to poor training, lack of a suitable scientific education, poorly designed experiments, and inappropriate published photographs in training materials.

Projectiles (e.g., bullets) impacting or traversing materials often can be expected to produce secondary projectiles. These secondary projectiles can consist of fragments of the materials struck or fragments of the projectile itself in the case of a hard target surface such as concrete or steel. The type of secondary projectile which predominates depends on the hardness of the initial projectile relative to the hardness of the material with which it interacts. In controlled experimental work, the secondary projectiles can be studied using high-speed photography and/or by placing “witness papers” near the point of impact or projectile exit. Witness papers are specially prepared surfaces, commonly white paper supported by a frame, used to reveal the path of a projectile or secondary projectiles. Of course, in “real world” case investigations, neither of these recording mediums is typically available. Any record produced of such secondary projectiles will depend upon the fortuitous proximity of surfaces capable of retaining evidence of such secondary projectiles.

Published photographs of a bullet traversing a blood-saturated sponge are very misleading. Something in the vicinity of 90% to 95% of the weight of a blood-soaked sponge or section of open cellular foam is due to the blood contained therein. This is not a good experimental model for shots traversing many regions of the human body. Only about 5% to 7% of the weight of a human body is blood. In addition, the blood is not evenly distributed throughout the body. In most regions and tissues in the body, the blood is confined to capillary beds. The function of the fine-diameter capillaries is to provide more intimate contact between the oxygen carrying red cells and somatic tissues dependent upon oxygen. Life-sustaining oxygen transport would be inefficient without hemoglobin and small-diameter capillaries. The capillaries have inside diameters of approximately 5 μ m. Some publications discussing blood spatter produced by gunshot wounds refer to drops with stain diameters of 1mm as being diagnostic for gunshot-derived blood spatter. This dimension is 200 times that of the capillary diameter. Thus, for a bullet traversing capillary-supplied tissue, no coalesced volumes of liquid blood are encountered. The bullet may carry tissue and fragments of capillaries with it and deposit them on a surface near the exit wound (or even on a surface near the entrance wound). In this circumstance, there will be no droplets of blood deposited. In actual cases, histological examination of the deposited tissue fragments has revealed fragments of capillaries with red cells lined up single-file within them. Again, there are no blood droplet stains. On the other hand, if the bullet encounters a volume of coalesced blood along its path, such as that contained in larger blood vessels or even the heart, fine droplets of blood can contribute to the spatter pattern. After a bullet has traversed capillary-supplied tissue, blood will flow into the wound channel, coalesce to form larger volumes, and may be available for spattering during a follow-on shot to the same area. Clothing which becomes saturated with blood flowing from a wound may behave like the blood-soaked sponge discussed above, if it is struck by another bullet. Additional ways in which gunshots can produce fine droplet spatter will be discussed.

The point needs to be made that special conditions are required in order for a gunshot to produce airborne droplet spatter patterns. Principally, there must be a volume of coalesced blood along the bullet path along with a suitable nearby target to collect and record the pattern of any blood droplets that are projected from the wound. These points will be illustrated using experimental models and actual case examples.

Blood Spatter, Gunshot, Shooting Reconstruction

Criminalistics Section - 2015

B113 The Hunt for Aaron Bassler: A Multidisciplinary Criminalistics Case Study Incorporating Proper Crime Scene Evidence Collection, DNA, Officer-Involved Shooting, and Firearms Comparison

Deborah R. Stonebarger, BS, Department of Justice, Redding Laboratory, 9737 Tanqueray Court, Redding, CA 96003*

After attending this presentation, attendees will better understand a criminalistic's case study that encompasses crime scene response, proper crime scene evidence collection, DNA, and firearms comparison.

This presentation will impact the forensic science community by reviewing a comprehensive criminalistics case that explores the inter-relationship between client agency investigations and the criminalistics laboratory.

On August 11, 2011, a gunshot homicide victim was found in a remote forest area of Mendocino County, CA, by the Mendocino County Sheriff's Office. The unknown suspect had defecated at the scene and the Mendocino County Sheriff's Office believed this to have good evidentiary value for a DNA and Combined DNA Index System (CODIS) search. Detectives from Mendocino County Sheriff's Office contacted a senior criminalist at the California Department of Justice Eureka Laboratory regarding submission of feces evidence left at a crime scene. The detectives were advised that the sample was inappropriate for DNA analysis. After determining there was no firearm evidence left at the scene, they were advised to return to the scene to look for a more appropriate sample such as a bottle, can, partially eaten food, or cigarette butt. Mendocino County Sheriff's Office personnel returned to the scene and collected a tinfoil marijuana joint.

On August 27, 2011, a second gunshot homicide victim was located in a remote forest area near the town of Fort Bragg, CA, also in Mendocino County. A witness to this shooting helped Mendocino County detectives identify Aaron Bassler as a possible suspect. Due to the apparent type of weapon used, the wilderness location of the homicide, and familiarity with the suspect, the Mendocino County Sheriff's Office detectives believed that Aaron Bassler was the suspect for both homicides. Another senior criminalist at the California Department of Justice Eureka Laboratory was called in to assist in processing the scene of the second gunshot victim. Among the items collected at the scene was a tinfoil marijuana joint. The first senior criminalist collected swabs from the marijuana joints at each scene and submitted the swabs to the California Department of Justice Redding Laboratory for DNA analysis. Due to the fact that the suspect had not been apprehended, a reference bloodstain was made from a blood sample from Aaron Bassler's previous Driving Under the Influence (DUI) submission. The DNA profiles from the evidence from both scenes were the same as Aaron Bassler's.

Two homicide victims in a small, rural county caused great concern for the citizens of Mendocino County. The Mendocino County Sheriff issued multiple press release statements declaring that apprehending the suspect was a top priority. A five-week manhunt ensued that involved Special Weapons And Tactics (SWAT) teams from Mendocino County, Humboldt County, Napa County, Sacramento County, and Alameda County as well as United States Federal Marshals, numerous search and rescue teams, and K-9 units. The suspect was able to elude the agents at length due to his familiarity with the remote surroundings, the very difficult terrain, and his survivalist mentality. At one point during the manhunt, Bassler was observed by an Alameda County SWAT officer and gunfire was exchanged. After he had fled the area, fired cartridge cases were collected from the rifle used by Bassler during this incident.

The manhunt finally came to a conclusion when Sacramento County SWAT officers shot and killed Bassler. The weapons from the officers involved in the fatal shooting of Bassler as well as Bassler's rifle were submitted to the first senior criminalist for comparison to the fired cartridge cases from the second homicide scene and both officer-involved shootings. The cartridge cases were most likely fired from Bassler's rifle.

Crime Scene, DNA, Firearms Comparison

B114 Polymer Replication of Reference Bullets Using Advanced Casting and Metal-Coating Techniques

Thomas B. Renegar, BS, 100 Bureau Drive, Mail Stop 8212, Gaithersburg, MD 20899; Xiaoyu A. Zheng, MS, 100 Bureau Drive, Mail Stop 8212, Gaithersburg, MD 20899; Robert M. Thompson, BS, NIST, Office of Special Programs-Forensic Sciences, 100 Bureau Drive, Mail Stop 8102, Gaithersburg, MD 20899; Theodore V. Vorburger, PhD, 100 Bureau Drive, Mail Stop 8212, Gaithersburg, MD 20899; Junfeng J. Song, MS, 100 Bureau Drive, Mail Stop 8212, Gaithersburg, MD 20899; Johannes A. Soons, PhD, NIST, 100 Bureau Drive, Mail Stop 8223, Gaithersburg, MD 20899; and James H. Yen, PhD, Statistical Engineering Division, NIST, 100 Bureau Drive, Mail Stop 8980, Gaithersburg, MD 20878-8980*

After attending this presentation, attendees will understand the concepts of creating polymer replicas from reference bullets. Vacuum-degassing and pressurization techniques are discussed for removing micro-bubbles. Sputter-coating techniques are also discussed which give hard-coating surfaces to the replicas, thereby increasing the durability.

This presentation will impact the forensic science community by providing a high-quality method for the transfer of evidence between jurisdictions. This normally results in a chain-of-custody issue; however, the transfer of replicas instead of original evidence allows agencies to work together in solving violent crimes. The sharing of evidence could lead to breakthroughs in criminal cases where it was not previously possible.

This presentation describes the polymer casting/replication and metal-coating techniques that are being used at the National Institute of Standards and Technology (NIST) to improve the quality and durability of replicated reference bullets using polymer casting methods.

Tool marks created by a firearm on a bullet or cartridge case are very important in the forensic examination of violent crimes. In many cases where violent crimes are committed in multiple jurisdictions, the transfer of ballistic evidence from one jurisdiction to another would be beneficial in helping to solve these cases; however, the transfer of ballistic evidence from one laboratory to another is typically not possible due to chain-of-custody requirements. The replication of ballistic evidence using polymer casting techniques is a perfect solution to this problem. High-quality replicas of the bullets can be distributed and analyzed, preserving chain-of-custody requirements of the original evidence.

NIST has been developing a polymer replication technique based on earlier work at the Bundeskriminalamt in Germany.¹ A vacuum-degassing process has been developed that removes the majority of micro bubbles from the replication materials during mixing. Pressurized chambers are also used during the curing phase to eliminate any remaining bubbles from the material so that near-perfect replications of the original bullets are created.

The process of making a replica bullet is explained with emphasis on the vacuum-degassing and pressurization steps that are necessary in creating clean replicas free of micro-bubbles. Comparisons of the replicas to the original master bullets are performed by measuring or imaging the striated features. Optical bright field microscopy is used for qualitative comparisons and high-resolution measurements of the surface topography are performed using disk-scanning confocal microscopy and surface profilometry. Analysis of the surfaces using mathematical correlation algorithms is then performed to make objective comparisons of the replicas and quantify their similarity to the master bullets.

The NIST Standard Reference Material (SRM) 2460 Bullets are used as a basis for the replications. The SRM bullets were originally manufactured using a computer numerical control-based diamond turning process. This is a highly repeatable process that precisely machines the striated markings onto the bullet surface. The surface topography of these bullets is well defined and each one is virtually identical to the other. Validation of the replication process is possible through the quantitative analysis of the SRM bullets and their replicas.

Durability of the replicas has also been investigated. Due to the relatively soft nature of polyurethane, additional hardening of the surfaces is required for the replicas to be durable enough for forensic work. A metal sputter-coating process is used that coats the replicas with a very thin layer of metal. The specific type of metal coating can be varied depending on the application. A thin layer of gold coating is an excellent barrier to tarnish/aging of the base material. It also reduces static charging and can be useful if scanning electron microscopy analysis is utilized in the examination. If additional hardness is required to reduce the risk from handling or abrasives, the gold coating can also be combined with other elements such as chromium or platinum. These coatings leave an excellent finish that is both durable and good for use with optical inspection methods. The sputter-coating process will be discussed, as well as additional correlation analysis showing comparisons from before and after the coatings.

After attending this presentation, attendees will appreciate the challenges of conducting evidence-based research to establish a scientific procedure for quantitative error rate reporting to support ballistics and tool mark identifications in the United States.

This presentation will impact the forensic science community by explaining a new method, Congruent Matching Cells (CMC), developed for accurate ballistics identification and error rate calculation.

Side-by-side image comparisons for ballistic identification have more than a 100-year history; however, as stated in a 2008 National Research Council Report: (1) “The validity of the fundamental assumptions of uniqueness and reproducibility of firearms-related toolmarks [sic] has not yet been fully demonstrated.”; (2) “Recent court decisions in which admissibility of firearms toolmark [sic] evidence was in question have generally accepted that the field has validity but have refused to accept ‘exclusion of all other firearms’ arguments.”; and, (3) “Since the basis of all forensic identification is probability theory, examiners can never really assert a conclusion of ‘identification to exclusion of all others in the world,’ but at best can only assert a very small probability of a coincidental match”.¹⁻²

However, for DNA-based identifications, the 2009 National Academy of Sciences Report, *Strengthening Forensic Science in the United States: A Path Forward*, stated: “The courts already have proven their ability to deal with some degree of uncertainty in individualizations (with its small, but nonzero, error rate)”.³

It has been a fundamental challenge in forensic science to conduct evidence-based research for establishing a scientific procedure for quantitative error-rate reporting to support ballistics and tool mark identifications in the United States.

The National Institute of Standards and Technology’s (NIST’s) Forensic Topography and Surface Metrology Project seeks to support United States forensic identifications by developing novel physical standards and measurement systems. The research team has developed NIST Standard Reference Material (SRM) bullets and cartridge cases which are being used in the United States and foreign crime laboratories as reference standards.^{4,5} The team also developed topography measurement systems and correlation software for bullets and cartridge cases, which have been used in support of the 2008 National Academies Study and in a laboratory comparison of ballistic imaging systems in crime labs.^{4,6,7} In addition, results of two studies have shown a high-correlation accuracy using the NIST topography correlation system relative to a commercial system.^{6,8}

NIST researchers have recently developed the new CMC method for accurate ballistics identification and error-rate calculation. The CMC method is based on correlations of pairs of small correlation cells instead of correlations on the entire images. Three types of identification parameters are created for uniquely identifying correlated cell pairs originating from the same firearm. This enables an approach to calculating error rates based on the total number of correlation cells, the number of qualified CMC cell pairs, and the false positive and false negative identification probability for an individual cell pair. Validation tests of the CMC method have recently been completed using 40 cartridge cases fired with consecutively manufactured pistol slides. These tests include 717 Known Non-Matching and 63 Known Matching image correlations. The results do not produce any false positive or false negative identifications and so provide strong initial support for the effectiveness of the CMC method. A method for calculating error rates has also been developed using the CMC approach. It is believed that this method can be adapted to large databases and used for supporting ballistics identifications in court proceedings in a manner similar to methods used for DNA identifications.

B116 NIST Reference Ballistic Tool Mark Database for Research and Development of Identification Systems and Confidence Limits

*Xiaoyu A. Zheng, MS**, 100 Bureau Drive, Mail Stop 8212, Gaithersburg, MD 20899; *Johannes A. Soons, PhD*, NIST, 100 Bureau Drive, Mail Stop 8223, Gaithersburg, MD 20899; *Robert M. Thompson, BS*, NIST, Office of Special Programs-Forensic Sciences, 100 Bureau Drive, Mail Stop 8102, Gaithersburg, MD 20899; and *Mingsi Tong, PhD*, NIST, 100 Bureau Drive, Mail Stop 8212, Gaithersburg, MD 20899

After attending this presentation, attendees will understand how the National Institute of Standards and Technology (NIST) established its reference ballistic tool mark database. This includes meta data categorization, standard file exchange format, and test fire selection. Attendees will also learn why this reference database is important to the evolving field of objective firearm and tool mark analysis.

This presentation will impact the forensic science community by sharing how the research database and the infrastructure developed in this project provide a growing, shared, scientific knowledge base on the degree of similarity that can be found between marks made by different firearms and the variability in marks made by an individual firearm. This is achieved through a large variety of challenging datasets representing: (1) test fires conducted using consecutively manufactured barrels, slides, firing pins, and other firearm parts; (2) test fires conducted using the same firearm, with large numbers of intermediate firings to represent varying degrees of firearm wear; and, (3) test fires conducted using different brands of ammunitions.

The database contains test fires characterized by using state-of-the-art measurement equipment and measurement protocols at NIST. The database will drive the development and validation of mathematical criteria, algorithms, and systems for objective firearms identification. This is achieved through a unique focus on challenging scenarios, such as consecutively manufactured firearm components, persistence firings, and different ammunition types. These research datasets cannot be obtained from existing forensic databases such as the National Integrated Ballistic Information Network (NIBIN). It is not economically feasible for a single entity such as a university or system developer to generate the variety of data sets required for broadly applicable results. The database will contain both reflectance microscopy images and 3D surface topography data to ease the transition to 3D surface topography metrology.

The challenging identification scenarios provide researchers, for the first time, with the large variety of data needed to assess worst-case variability and repeatability, providing a path to the development of scientifically justified methods that yield identification results with well-characterized, quantitative confidence limits.

The project objective is an open-access research database of bullet and cartridge reference data, consisting of traditional reflectance microscopy images and 3D surface topography. The database will foster the development and validation of advanced algorithms, mathematical similarity criteria, and quantitative confidence limits for objective ballistics identification.

The 2009 National Academy of Sciences Report, *Strengthening Forensic Science in the United States: A Path Forward*, called into question, among other issues, the objectivity of visual tool mark identification by firearms examiners.¹ The National Academy of Sciences recommended development of objective tool mark identification criteria and error-rate estimates. Industry, academia, and government laboratories are pursuing two promising approaches toward this goal: (1) development of mathematical criteria and advanced algorithms for the objective and automated identification and scoring of potential matches; and, (2) supplementing traditional reflectance microscopy images with 3D surface topography measurement data.

Development and validation of both of these approaches to objective tool mark identification are hindered by a lack of access to tool mark data sets that: (1) represent the large variety of ballistic tool marks encountered by tool mark examiners; and, (2) represent challenging identification scenarios, such as those posed by consecutively manufactured firearms components. It is not economically feasible for individual companies or institutions to generate their own data sets. This makes it difficult for these entities to objectively evaluate their solutions. During the symposium held at NIST entitled, "Measurement Science and Standards in Forensic Firearms Analysis 2012," one of the priority requests from the attendees was the construction of a database where bullet, cartridge case, and tool mark surface data can be shared between researchers to facilitate testing, refinement, and comparison of new systems, methods, and algorithms.

Criminalistics Section - 2015

The database will provide the representative variety of tool mark data required, ranging from crime laboratory test fires to test fires conducted using consecutively manufactured barrels, firing pins, slides, and other firearm surfaces. The database will contain both reflectance microscopy images and 3D surface topography data. The database will consist of indexed surface data acquired at NIST using state-of-the-art instruments and measurement procedures. Some of the data collected will be stored in a closed database for possible future application to the validation and comparison of correlation software.

The database will enable researchers to test and validate new approaches to objective, mathematics-based tool mark identification while easing the transition to 3D surface topography data. The database will provide a foundation for a scientific knowledge base on the degree of similarity that can be found between marks made by different firearms and the variability in marks made by an individual firearm. The current “fairly limited” knowledge base is a fundamental barrier to the development and validation of objective mathematical similarity criteria and associated confidence limits applicable to a broad range of firearms and ammunition brands.¹

B117 Improved Congruent Matching Cells (CMC) Method for Optical Images Identification of Cartridge Cases

*Mingsi Tong, PhD**, NIST, 100 Bureau Drive, Mail Stop 8212, Gaithersburg, MD 20899; *Junfeng J. Song, MS*, 100 Bureau Drive, Mail Stop 8212, Gaithersburg, MD 20899; *Wei Chu*, 100 Bureau Drive, Mail Stop 8212, Gaithersburg, MD ; and *Robert M. Thompson, BS*, NIST, Office of Special Programs-Forensic Sciences, 100 Bureau Drive, Mail Stop 8102, Gaithersburg, MD 20899

After attending this presentation, attendees will understand a new theory of ballistics identification, the implementation of this method, and the applications on cartridge case identifications.

This presentation will impact the forensic science community by applying the proposed CMC method to cartridge case identification. The method can decrease the effect from “invalid areas” of images and improve the accuracy of identification.

The CMC method was invented by the National Institute of Standards and Technology (NIST) with the ultimate goal of providing objective and high-accuracy ballistics identifications and evidence searches. The CMC method is based on the correlation of pairs of small correlation cells instead of correlation on entire images to identify the “valid correlation areas” and eliminate the “invalid correlation areas.” Four identification parameters are proposed for uniquely identifying correlated cell pairs originating from the same firearm. The correlation conclusion (matching or non-matching) is determined by the qualified CMC numbers $C \geq 6$.¹ This method has already been validated by a set of 780 pair-wise 3D topography images captured on 40 cartridge cases fired from handguns with ten consecutively manufactured pistol slides; however, most ballistics images stored in current national databases are optical intensity format.² As a result, the reliability of applying the CMC method on optical intensity images is an important issue.

To verify the effectiveness of the CMC method on the optical images, this presentation initially introduces the implementation of the CMC method and provides a fast correlation method and the strategy for threshold determination. Then the optical intensity images captured on the same set of 40 cartridge cases under the top-ring lighting source (which provides uniform light conditions) are correlated and analyzed. This includes 780 correlations of 63 pairs of matching images and 717 pairs of non-matching images. The tests of the method do not produce any false identification (false positive) or false exclusion (false negative) results, which supports the CMC method and the identification criterion $C=6$ for firearm identifications using optical intensity images. To improve the identification accuracy of the CMC method, a new method has been developed to process cell correlations at each rotation angle and combine the forward and backward comparisons to improve the identification accuracy. In the initial test, the CMC method identifies all of 780 correlations correctly. Compared with the result of the original method, the improved result shows a larger gap between the matching and non-matching correlations, which proved that the improved CMC method is effective in improving the accuracy of identification. Based on results of the study, it is considered that the principle of the CMC method is effective in firearms identifications in both 3D topography images and optical images of cartridge cases. The proposed identification criterion $C=6$ is also working well in current experiments.

B118 Toward a Novel, Fast, and Accurate 3D-Topography Imaging and Analysis System for Firearm Forensics

*Ryan Lilien, PhD**, Cadre Research Labs, 212 W Superior Street, Ste 503, Chicago, IL 60654; *Todd J. Weller, MS*, 455 7th Street, Rm 608, Oakland, CA 94607; *Marcus Brubaker, PhD*, Cadre Research Labs, 212 W Superior Street, Ste 503, Chicago, IL 60654; and *Pierre Duez, MS*, Cadre Research Labs, 212 W Superior Street, Ste 503, Chicago, IL 60654

After attending this presentation, attendees will be familiar with a novel 3D imaging and analysis system, the image acquisition technology, and the results of several cartridge casing matching experiments. This presentation will describe TopMatch-GS 3D, an accurate, fast, and low-cost 3D imaging and analysis system for cartridge casings.^{1,2}

This presentation will impact the forensic science community by educating attendees on the latest generation of technology for 3D tool mark imaging and analysis. The use of a confidence score and interpretable match results will provide practitioners with a firm foundation on which to place identification results.

The work proposes that the 3D scanning system, TopMatch-GS 3D, is capable of acquiring high-resolution surface scans, visualizing these scans, and accurately comparing/matching pairs of casing scans. The study investigated if the matching algorithm is capable of recognizing known matches with high accuracy while keeping the rate of false positives to near zero.

The prototype TopMatch-GS 3D scanner incorporates the GelSight[®] retrographic sensor to measure 3D surface topography at a resolution of 1.4 microns per pixel.^{3,4} The system was evaluated on a large data set containing casings from several hundred 9mm Luger[®] firearms, representing more than 20 firearm manufacturers and seven ammunition types. The firearms come from several crime laboratory reference collections and were not selected on their ability to produce strong tool marks. The casings represent the types of evidence and test-fires seen in a real-world setting. They contain milled, filed, granular, and striated marks as well as poorly marked casings. Data collection took place both in-house and at several collaborating California crime laboratories. Participants across these locations include trained firearms examiners, technicians, forensic science students, and university faculty.

The algorithm's match score is a function of the similarity between the casings' true breech-face impression and their aperture shear. For breech-face impression comparison, automatically identified distinctive features (corresponding to informative microscopic tool marks) are used to match and align two casings. By requiring spatial coherence of matched features, the methodology is able to strongly indicate when two casings were fired through the same firearm. In contrast to cross correlation-based methods, feature-based techniques compute the match score using only the portions of the surface identified as informative (i.e., the matching microscopic tool marks). The algorithm compares aperture shears by first extracting the linear shear profile and then aligning two profiles while accounting for baseline correction and warping.

The scoring function is a confidence score where each candidate match (pair of casings) is scored based on the likelihood that the two casings were fired through the same firearm. Unlike other systems, the TopMatch score reflects the true confidence of the match. The confidence score allows examiners to efficiently limit their search. In other words, examiners only need to consider candidate matches that score above a threshold.

The TopMatch system is able to match casings with high accuracy. True positives (known matches) have extremely high scores while true negatives (known non-matches) have low match scores. There are virtually no false positives (i.e., known non-matches mistakenly identified as a match).

The TopMatch-GS 3D imaging and analysis technology represents a promising new method for measuring and correlating the true 3D surface topography of cartridge casings. The results from several deployment studies and the large set of real-world casings demonstrate accurate matching results with an extremely low false positive rate (near zero as of the time of this writing).

B119 Evaluating the Gray Scale Response Difference Associated With Bullet Comparisons Using Optical Microscopy

Victoria J. Richards, MS, Douglas County Sheriff's Office, 15345 W Maple Road, Omaha, NE 68116; David G. Howitt, PhD, University of California, Dept of Chemical Engineering, Davis, CA 95616; Frederic A. Tulleners, MA, UC Davis, Forensic Science Graduate Program, 1909 Galileo Court, Ste B, Davis, CA 95618; and Robert B. Kimsey, PhD, University of California, Forensic Science Graduate Program, 1909 Galileo Court, Ste B, Davis, CA 95618*

After attending this presentation, attendees will gain a greater appreciation for how tedious and delicate the task of bullet comparisons is and understand that the inherent error associated with these types of comparisons can be overcome with the proper approach.

This presentation will impact the forensic science community, specifically the firearms examiner faction, by providing results from a controlled experiment with a known bullet profile. The reproducibility of this research will provide an opportunity for a starting point for future methodology that produces bullet comparisons with greater reliability.

Firearms examiners have long been interested in a method that would image the striae of a bullet so that it could be entered into a database for subsequent comparison to other bullets. As the development, use, and application of these databases grew, so did the problems associated with them. The algorithms were breaking down and the software was not functioning at the level of precision expected by firearms examiners, thus analysts stopped using the databases and returned to the traditional laborious methods of bullet analysis using the comparison microscope; however, the use of the comparison microscope is not without its own set of limitations. When using a comparison microscope, two separate stages with two separate light sources are necessary because the determination of the distribution of striae on a bullet is sensitive to bullet position and orientation. It is suggested that many of the problems associated with bullet-based database systems are directly related to methods in which images are captured, along with the number and type of images.

The goal of this research was to ultimately determine if bullet comparisons using optical microscopic imaging were possible, rather than live bullet-to-bullet comparisons. Once that was determined, which microscope would produce the best results for bullet comparison utilizing captured images and the minimum number of images that should be taken of a single land impression to account for all potential variations in bullet profiles was identified. To identify profile measurement error inherent in orientation and rotational and translational mis-orientation, the profile of a National Institute of Standards and Technology (NIST) Standard Reference Material (SRM) 2460 standard bullet was measured while misoriented in systematic ways using a light microscope. These measurements were then repeated with a Zeta 3D-20 optical microscope and a Leica® FSC comparison microscope to determine which microscope produced the greatest correspondence for misoriented NIST bullet profiles. The method applied utilized captured images that were converted into light contrast profiles, which were a representation of the bullet surface based on light intensities. From these profiles, identified peaks and valleys were grouped into resolution bins or segments of a particular length which were used to subdivide the land impression of the bullet and discriminate peaks and valleys. The results showed that the light microscope produced the highest level of correspondence with 100% total peak correspondence for both laterally and rotationally shifted profiles, 330µm and 6° respectively, with a 20µm bin resolution.

Based on this study it was concluded that bullet comparison through the use of images captured by optical microscopy is possible. It is thus suggested that something similar to the Zeiss Universal light microscope with reflected through-the-lens illumination be used for this methodology for bullet analysis and comparison using a bin resolution no less than 15 microns. With this microscope, the minimum number of images required to account for potential misorientation, or bullet profile variations, are 11 images per land impression.

B120 Critical Angles for 9mm Parabellum Bullets

Peter J. Diaczuk, BS*, 445 W 59th Street, New York, NY 10019-2925; and Thomas Kubic, JD, PhD, 8 Pine Hill Court, Northport, NY 11768

The goal of this presentation is to introduce attendees to the angle at which a ricochet will no longer occur when a bullet strikes some common substrates.

This presentation will affect the forensic science community by providing data that can be used as background when assessing a ricochet at a shooting scene.

Determining the angle at which a bullet will successfully ricochet is essential information when a shooting investigation involves indirect fire. This information provides the forensic scientist with fundamental data required for the scientific reconstruction and assessment of a shooting scene. Depending upon the substrate, the bullet's design, velocity, construction, and its angle of impact, a bullet may fail to ricochet upon impact or the bullet will successfully ricochet. Knowledge of bullet behavior with common substrates provides valuable information for scientific investigations of shooting scenes where bullets have impacted intermediate surfaces. A timely and accurate scene reconstruction is imperative in both the investigative and the adjudicative stages of a shooting incident.

Bullets discharged from firearms have a considerable amount of kinetic energy and achieve high velocity during the very short time they are accelerating down the bore of the firearm. Even accounting for some frictional losses as it is forced through the bore, the once-stationary bullet emerges as a fast-moving energetic projectile.

A bullet that is discharged from a firearm can ricochet off of the many different surfaces present at a typical shooting scene. Although bullets will behave differently depending upon the material they encounter, they are nevertheless bound by the laws of physics.

Potential ricochet surfaces may be categorized based on how the bullet interacts with the substance. Hard surfaces traditionally remain intact after low-angle bullet ricochet because they will not yield to the bullet's impact energy. Materials such as concrete, marble, granite, and steel are just a few examples that fall into this category. Bullet ricochets off of hard unyielding surfaces consistently have ricochet angles (the angle created between a line designating the bullet path and a line designated by the substrate surface) that are less than the bullet's angle of impact (the acute angle at which the bullet approaches the substrate surface).¹ Soft surfaces will not remain intact but instead will deform, deflect, or fail entirely, yielding to the bullet's impact energy. Materials such as wood, turf, sand, paneling, wallboard, thin automobile sheet metal, and water are just some examples of surfaces that fall into this category. Bullet ricochets off of relatively soft yielding surfaces routinely have ricochet angles that are greater than the impact angle of the bullet.² When a bullet is fired at either of these types of materials, whether hard or soft (i.e., unyielding or yielding, respectively), there is an angle at which a ricochet will no longer occur. At (and above) this "critical angle" the bullet may break apart into fragments after hitting the surface in the case of a hard unyielding substrate or it may remain intact, to either penetrate (embed but not exit) or perforate (enter and exit) the material in the case of a soft yielding substrate.

The critical angle for the 9mm full metal jacket bullet used in this study was determined to be between 7° and 8° for gypsum drywall, between 5° and 6° for automotive sheet metal, between 11° to 15° for sand, and approximately 15° for heavy steel plate, marble, and modular concrete block. For the purposes of determining the critical angle for the unyielding substrates, the retained weight of the bullet was used as the criterion to decide whether the angle had been reached. Once the recovered bullet lost more than 5% of its original mass, the critical angle was considered achieved; however, it must be appreciated that a fast-moving bullet with 95% of its original mass must still be treated with respect.

Ricochet, Critical Angle, Shooting Reconstruction

B121 A Study of the Presence of Gunshot Residue in Pittsburgh Police Stations Using SEM/EDX and LC-MS/MS

Leah Ali, BS, 700 Forbes Avenue, Apt 610, Pittsburgh, PA 15219; Kyle Brown, Duquesne University, 600 Forbes Avenue, Pittsburgh, PA 15282; and Stephanie J. Wetzel, PhD, Department of Chemistry and Biochemistry, 600 Forbes Avenue, Pittsburgh, PA 15282*

After attending this presentation, attendees will be informed about a novel approach that was used in the investigation of the likelihood of Pittsburgh police vehicles and stations being sources of both inorganic and organic secondary Gunshot Residue (GSR) contamination. Attendees will also better understand how to analyze both inorganic and organic GSR from a carbon-coated adhesive aluminum stub.

This presentation will impact the forensic science community by investigating the presence of both inorganic and organic GSR contamination in police stations and vehicles — something that has yet to be investigated. Several studies have shown that environmental sources such as cars, fireworks, or paints can produce particles that may be misinterpreted as characteristic inorganic GSR. Yet, by testing for both organic and inorganic GSR, this possibility of misinterpretation by environmental sources could potentially be eliminated, which in turn would greatly enhance the significance of the evidence.

A police station or vehicle contaminated with GSR could lead to arrested individuals testing positive for GSR even though they have neither recently fired a gun nor been in the vicinity of a fired gun. This in turn could result in the incrimination of the innocent as well as lessen the legitimacy of a positive GSR result. Due to the risk of secondary transfer of GSR by a police vehicle or station onto the suspect prior to GSR sampling, it is necessary to create a baseline for the amount of GSR present in a police station or police vehicle. The potential of police stations and vehicles being sources of secondary inorganic GSR contamination has been investigated using Scanning Electron Microscopy with Energy-Dispersive X-ray Analysis (SEM/EDX); however, the presence of organic GSR contamination has not been examined.

This research takes a novel approach by investigating the likelihood of Pittsburgh police vehicles and stations being sources of both inorganic and organic secondary GSR contamination. Seventy-three samples were collected from four Pittsburgh police stations and vehicles using carbon-coated adhesive aluminum stubs. The samples were automatically analyzed using the SEM/EDX for the presence of non-crystalline particles containing approximately 10% by weight antimony, barium, and lead. These particles were classified as characteristic inorganic GSR, while non-crystalline particles containing various combinations of lead, antimony, and barium with aluminum, titanium, and zinc were classified as consistent with inorganic GSR. For a sample to be considered positive for GSR, there must have been at least three characteristic inorganic GSR particles present. Only one characteristic inorganic GSR particle was found; no sample was classified as positive for GSR. These results suggest there is a small potential of secondary transfer of inorganic GSR by a police vehicle or station onto a suspect. To test for the presence of organic GSR, these same 73 samples were then extracted with methanol and analyzed using Liquid Chromatography with Tandem Mass Spectrometry (LC-MS/MS). Optimized liquid chromatography parameters and an optimized multiple reactions monitoring scanning method were developed to obtain the greatest sensitivity for the following investigated compounds: akardite II, ethyl entralite, diphenylamine, N-nitrosodiphenylamine, 4-nitrodiphenylamine, and 2-nitrodiphenylamine. The limit of detection for each of the above compounds was found to be 0.53, 0.40, 1.18, 3.78, 2.33, and 2.33 nmol L⁻¹, respectively. Recovery percent from spiked SEM stubs was also investigated.

Gunshot Residue, SEM/EDX, LC-MS/MS

B122 Detection of Organic Components of Gunshot Residue (GSR) of Carbon SEM Stubs by Raman Spectroscopy

*Karyn Crawford**, 1616 Spring Valley Drive, Apt 28, Huntington, WV 25704; *Lawrence E. Wayne, BS*, Forensic Analytical Laboratories, Inc, 3777 Depot Road, Ste 409, Hayward, CA 94545; *Jacobus Swanepoel*, 3777 Depot Road, Ste 403, Hayward, CA 94545; and *Lauren L. Richards-Waugh, PhD*, Marshall University, 1401 Forensic Science Drive, Huntington, WV 25701

After attending this presentation, attendees will better understand the analysis of organic components of GSR by Raman spectroscopy and the increased probative value of the data produced. Attendees will further understand initial efforts at development of an analytical protocol which can identify both organic and inorganic components of GSR using a standard 12.7mm Scanning Electron Microscopy (SEM) stub with carbon adhesive tab.

This presentation will impact the forensic science community by demonstrating the applicability of Raman spectroscopy to an analysis scheme which currently relies on Scanning Electron Microscopy with Energy-Dispersive X-ray Spectrometry (SEM/EDS) to identify individual particles having a specific morphology and elemental composition.

Current methods of GSR analysis concentrate on identification of the inorganic components of ammunition primers. Single particles with morphology indicative of formation in a high heat environment and containing the elements lead, barium, and antimony are considered characteristic of GSR. SEM/EDS is the widely accepted method to determine both elemental composition and morphology. Although this is a very effective method, the probative value of inorganic GSR analysis is limited. Not only are there limitations on the sample containing three component particles, but current and future formulations of “green” lead-free ammunition will lead to an increasing probability of false negatives.

The organic component of the GSR has not been utilized during analysis thus far. Chromatography with mass spectrometry has been proposed as a way to identify the components of these organic compounds, but at the expense of the sample. There would be no way to identify if the inorganic components are present after this examination. With recent advancements in Raman spectroscopy technology, new techniques are able to be developed.

This study introduces early research into the ability to detect and characterize organic residues deposited on the standard 12.7mm SEM stubs, while still allowing for subsequent traditional SEM/EDS analysis.

Previously published results of the viability of organic GSR analysis by Raman spectroscopy were reproduced by firing several types of ammunition at short range into cloth targets and confirming the presence of particles of partially combusted propellant. The spectra of the unfired propellant were compared to the partially burnt propellant picked off of the fabric and were compared and observed to be consistent. To expand the scope of the initial analysis, 12.7mm SEM stubs with adhesive carbon tabs were mounted three inches on either side of the cloth target. Spectra consistent with results from unburnt propellant were able to be obtained by targeting individual particles on the surface of the carbon tab. Positive results show that it is possible to identify organic GSR components even in the presence of broad, dominant carbon D band at $1,350\text{cm}^{-1}$ and G band at $1,582\text{cm}^{-1}$. By using this non-contact and non-destructive approach, the GSR stub is available to be used for subsequent analysis on the SEM/EDS.

The next phase in the research involved a more realistic collection scenario. After each test firing, the shooter’s hands were sampled with individual GSR stubs in accordance with normal collection of inorganic GSR. Initial manual scans detected a small number of particles consistent with organic components of the propellant of the discharged ammunition. Although the initial number of particles detected was small, the findings are considered an important proof of concept that organic portions of GSR can be detected on samples using existing collection protocols.

Future areas to be researched are the optimization of instrument parameters to be able to accurately detect organic GSR particles, correctly characterize and classify particles by propellant type, and implement the use of software mapping features to set up an automated run similar to the inorganic GSR analysis by SEM.

This study indicates that it is possible to detect organic components of GSR on a standard 12.7mm SEM stub with adhesive carbon tab using already existing collection techniques. Since organic GSR shows far more variation both by manufacturer and even by individual types of ammunition by the same manufacturer, it may be possible to identify differing types of propellants, greatly increasing the probative power of GSR analysis.

Gunshot Residue, Raman, Organic

B123 Development of a Spectral Camera for Estimating the Age of Bloodstains in Casework

*Gerda Edelman**, Netherlands Forensic Institute, Laan van Ypenburg 6, The Hague, 2497 GB, NETHERLANDS; and *Maurice Aalders, MD, Meibergdreef 9, Amsterdam, NETHERLANDS*

After attending this presentation, attendees will understand the principles of hyperspectral imaging and the chemical reactions taking place within a bloodstain.

This presentation will impact the forensic science community by showing the possibilities and limitations of a technique for age estimation of bloodstains at the crime scene.

If the age of bloodstains could be determined, this would provide investigators with valuable information regarding the timeline of events. Although several techniques for the age estimation of bloodstains have been explored in forensic laboratories, no method has yet been applied in forensic investigations. The transition from laboratory measurements to crime scene analysis brings some typical challenges. While ideal substrates are selected in a laboratory setup, many different and far-from-ideal substrates can be encountered at a crime scene. Likewise, the measurement setup is less controlled.

Recently, it was demonstrated how diffuse reflectance spectroscopy could be used to measure the concentration change of oxyhemoglobin, methemoglobin, and hemichrome, all reaction products of hemoglobin, in order to estimate the age of bloodstains in a laboratory setup without destroying or even touching the sample. Measurements were demonstrated on 40 bloodstains performed at ages ranging from fresh to 200 days old and estimated the age with an error margin of approximately 20%. This method has now been adapted to the specific requirements of forensic practice. A wireless spectral camera was introduced to replace the optical fibers used for point measurements in the laboratory. By combining spectroscopy and digital imaging, spectral imaging enables investigators to record the reflectance spectra and the distribution of many bloodstains simultaneously. To be able to perform measurements on (non-ideal) substrates possibly found at the scene, the algorithm used for the age estimation was adapted to correct for background absorptions.

The developed technique was successfully tested at a simulated crime scene in which bloodstains of five different ages were deposited. The absolute error of the age estimation task increased with age, with a median relative error of 13.4% of the actual age. Finally, the technique was applied in several real murder cases. In these cases, the research questions were twofold: (1) what is the age of these bloodstains; and, (2) were these bloodstains deposited during the same event?

Regarding the first question, when an absolute age estimation is asked, the influence of humidity and environmental temperature on the speed of the chemical reactions has to be taken into account. When this information is not available, it may be possible to perform a relative age estimation, which gives investigators information about the sequence of events.

In this presentation, the theory of bloodstain age estimation and spectral imaging is explained, followed by a description of the experimental verification and several case examples. Insight is given not only in the possibilities of this technique but the limits and challenges of this technique in forensic practice are also described. Applied in casework, this technique provides new objective information which can be used by investigators to create a timeline of events.

Spectral Imaging, Bloodstain Age, Timeline

B124 DNA Methylation Patterns as Markers in Forensic Investigation

*Deborah Silva, MS**, 118 Zamora Avenue, Apt 308, Miami, FL 33134; *Joana Antunes, MS*, Florida International University, 11200 SW 8th Street, Lab OE294A, Miami, FL 33714; *Kuppareddi Balamurugan, PhD*, University of Southern Mississippi, School of Criminal Justice, Hattiesburg, MS 39406; *George T. Duncan, PhD*, Broward County Crime Lab, 201 SE 6th Street, Rm 1799, Fort Lauderdale, FL 33301; *Clarice Alho, PhD*, PUCRS-FABIO, Av Ipiranga, Porto Alegre, BRAZIL; and *Bruce R. McCord, PhD*, Florida International University, Dept of Chemistry, University Park, Miami, FL 33199

After attending this presentation, attendees will understand the application of epigenetics markers in forensic casework and the importance of this new tool of identification in the resolution of a crime scene.

This presentation will impact the forensic science community by providing crucial information on the development/validation of DNA methylation markers for forensic use. The new and improved technique for the identification of cell type and age will provide the community with new and improved methods to interpret the crime scene.

Body fluids recovered from crime scenes are considered one of the most important types of evidence in forensic cases. DNA obtained from body fluids can be used to identify the donor of the biological material but as presently used it cannot reveal the tissue source or the possible age of the donor. Determining the type and origin of the fluid can provide important assistance in reconstructing crime scenes. DNA presents the ideal source for identification of tissue type since it provides quantitative results and is more stable than RNA. In addition, the extracted DNA target is already present in the laboratory.

DNA methylation is an epigenetic modification involved in transcriptional regulation.¹ It is known that methylation is important in cell differentiation and genomic loci are differentially methylated between tissues. Because of this, different methylation patterns between tissues and cells can provide the basis of an assay for body fluid identification. The ability to determine the age of the sample donor based on DNA would also be a powerful tool for forensic investigation. Human ageing is associated with epigenetic modifications such as DNA methylation. Several studies have investigated biomarkers for ageing which can be used to track donor age, presenting practical implications in forensic analysis.^{2,3}

The most common body fluids found at crime scenes are blood, semen, and saliva. A set of epigenetic markers, C20orf117, ZC3H12D, BCAS4, and FGF7, has been developed which produce unique and specific patterns of DNA methylation that can be used to identify these body fluid types; however, to ensure the efficiency of these epigenetic markers, developmental validation studies needed to be performed to determine the conditions and limitations of this new tool for forensic analysis.⁴ For this research, all validation studies were performed according to Scientific Working Group on DNA Analysis Methods (SWGDM) guidelines. Also, five genes previously found to be DNA methylation age-associated, NPTX2, TRIM58, GRIA2, KCNQ1DN, and BIRC4BP, were tested for prediction of age using a variety of body fluids and a pyrosequencing system.³ DNA was extracted and bisulfite conversion was performed using the Epitect® Bisulfite Kit. Bisulfite modified DNA was then amplified using specific primers for methylated target regions. The last step was analysis by pyrosequencing. All pyrosequencing reactions were performed using the PyroMark® Q24 Pyrosequencer. Data analysis was performed using the PyroMark® Q24 assay software for CpG methylation quantitation and the corresponding percent methylation values for each site and the data were displayed as a pyrogram.

The versatility of these new markers will be presented by showing the results of validation studies on sensitivity, human specificity, age, and mixture resolution. When testing the markers using different species samples, amplification occurs not only for human DNA but for some animal samples; however, when the amplified DNA is pyrosequenced, the sequencing primer increases the specificity and eliminates results from any non-human samples. All the other samples show a pyrogram equivalent to the one obtained for the negative control. In another test, samples were degraded by being heated at different temperatures. All degraded samples showed good pyrosequencing results. In a study examining the effect of Polymerase Chain Reaction (PCR) inhibition, all samples were amplified and showed good pyrograms when hematin (0.08mM) and humic acid (0.24mg/mL) were added before bisulfite modification. When these same inhibitors were added after bisulfite modification and before PyroMark® PCR, there were no satisfactory results. This data indicates that the purification process at bisulfite conversion removes inhibitors during the washing steps. Sensitivity and mixture studies were also performed. In general, the results generated indicate a good perspective for the overall validation of the tested markers.

This project was supported under award # 2012-DN-BX-K018 from the National Institute of Justice, Office of Justice Programs, United States Department of Justice. DNA Methylation, Body Fluid, Pyrosequencing

B125 Effects of Decomposition on the Recoverability of Biological Fluid Evidence

*Elena A. Bemelmans, BS**, Boston University School of Medicine, 72 E Concord Street, R-806, Boston, MA 02118; *Donald F. Siwek, PhD*, Dept Anatomy and Neurobiology, Program in Forensic Anthropology, 72 E Concord Street, Boston, MA 02118; *Robin W. Cotton, PhD*, Boston University School of Medicine, Biomedical Forensic Sciences, 72 E Concord Street, L1004, Boston, MA 02118; and *Amy N. Brodeur, MFS*, Boston University School of Medicine, 72 E Concord Street, R806, Boston, MA 02118

After attending this presentation, attendees will understand how decomposition and environmental factors can affect traditional methods for detecting and identifying blood and semen evidence as well as the ability to recover human DNA from such samples.

This presentation will impact the forensic science community by demonstrating that traditional methods of detection and testing may not readily identify blood and semen evidence present on the clothing of a decomposing body, indicating that alternate methods of testing and sampling should be considered.

Several factors that influence the rate of human decomposition have been described, including temperature, access by insects, humidity, and rainfall.¹ These environmental factors, as well as purge fluid released during decomposition, can also interact with any evidence deposited on the clothing of a deceased individual.² This present research assessed how these combined factors affected the detection and identification of blood and semen evidence.

A 35- to 45-pound feeder pig (Postmortem Interval (PMI) <3 hours) was placed on a grassy area within the Boston University Outdoor Research Facility for a period of 22 days during late spring, the temperature averaging 61.8oF. Aliquots of 30µl of either human blood or semen were pipetted onto 1"x1" sections of a 95% cotton T-shirt. Twenty-two samples of each type were placed on top of and underneath the pig, as well as a similarly weighted bag of sand (control). One bloodstain and one semen stain were collected each day for a period of 22 days from each location, yielding eight samples per day. Each sample was analyzed within 30 hours of collection.

The blood samples beneath the control showed that environmental factors influenced the results of testing. Rain caused dilution and diffusion of the bloodstains and the color of the stains changed from red-brown to green-yellow. Kastle-Meyer (KM) testing was positive for all samples and ABACard® HemaTrace® testing was positive for 14 of 22 samples, with the negative results occurring during days 12 to 22. Two stains that were negative at ten minutes turned positive shortly thereafter, suggesting that perhaps a longer development time may be required for compromised samples. The blood samples placed beneath the pig yielded positive KM results on all 22 days and positive HemaTrace® results through day ten. All bloodstains placed on top of the pig and control yielded positive KM and HemaTrace® results.

Semen samples from beneath the control began to show a decrease in fluorescence using an Alternate Light Source (ALS) by day three, and some areas of fluorescence occurred in a different location, indicating that the soluble components had diffused outward from the Original Region Of Deposition (ORD). Results for Acid Phosphatase (AP) and ABACard® p30 were mostly positive through day 16. By day 17, the ORD no longer fluoresced or yielded positive AP or p30 results. With the exception of day ten, sperm were identified on all samples. Semen results from beneath the pig showed that even on day one, the ORD were only weakly fluorescent and by day four, fluorescent regions began appearing outside of the ORD. These migrated regions of fluorescence yielded positive results with AP spot and p30 testing but showed few or no spermatozoa when examined microscopically. As the days passed, the ORD were no longer fluorescent and AP mapping and p30 testing yielded negative results; however, spermatozoa could still be identified in almost all of the ORD through day 22.

Semen samples collected from on top of the control showed that semen stains retained fluorescence and tested positive for AP, spermatozoa, and p30 through 22 days of testing. Semen samples collected from on top of the pig yielded similar results until day 16, when the fluorescence began to fade and AP testing did not yield traditional color changes associated with a positive result. By day 18, fluorescence was no longer visible with an ALS at 450nm or 495nm; however, Ultraviolet (UV) light yielded positive fluorescence when used during days 19 to 21. Spermatozoa and p30 were identified on samples saturated with products of decomposition, even when presumptive screening techniques were negative (450nm-495nm) or showed an altered appearance (AP).

DNA analysis results of select stains will be presented.

Blood, Semen, Decomposition

B126 Transfer of Sperm Cells During the Laundering Process

Alicia Swartz, MS, AFOSI, 4930 N 31st Street, Bldg 925, Forest Park, GA 30297; Lisa Burgee, MSFS, 901 R.S. Gass Boulevard, Nashville, TN 37216; and Elizabeth Richards, PhD, Defense Forensic Science Center, 4930 N 31st Street, Bldg 925, Forest Park, GA 30297*

After attending this presentation, attendees will understand the possible transfer of spermatozoa from one fabric item containing an original semen stain to another previously unstained fabric item during the laundering process.

This presentation will impact the forensic science community by potentially influencing how examiners in a forensics laboratory might treat future casework and what items of evidence criminal investigators might collect if the cases they encounter involve clothing items which have been laundered together.

During a sexual assault investigation, clothing and bed sheets are often collected due to their potential evidentiary value. Sperm cells recovered on such items may provide insight into the allegation but may also produce challenges when interpreting such results. The question then becomes whether the findings were from a direct deposition (potentially establishing sexual contact between suspect/victim) or from an unrelated event (transfer in the washing machine).

There have been several studies which have addressed the persistence of seminal fluid during the laundering process; however, the literature is scarce regarding the transfer of spermatozoa between items during the laundering process. Between the published papers specifically addressing transfer, there are conflicting reports on whether or not transfer occurs.

This project was designed as an initial study to assess the transfer of sperm during the laundering process. Seminal fluid was obtained from a fertility clinic and anonymous donors. A total of 24 cold water (18°C) washes were conducted using the same top-loading Maytag® Performa washer. Each wash cycle was completed using a “mini” water load and set to the “normal” wash cycle. Two types of detergents were tested, Liquid Tide® (phosphate) and Seventh Generation™ Detergent Pods (phosphate-free). Then 2mL of semen was deposited onto three types of “source” (stained) fabrics: 100% cotton panties, 100% cotton towels, and 60% cotton/40% polyester bed sheets. Each of the 24 wash cycles contained one “source” item and three equal size “receiving” (unstained) fabrics. Half of the stained “source” fabrics were air dried for 24 hours prior to washing and half were allowed to air dry for seven days. After washing, all fabrics were air dried.

Each “source” and “receiving” item was examined visually with an Alternate Light Source (ALS). Each item was then tested for acid phosphatase using AP Reagent solution and for the presence of the p30 protein using Seratec® PSA cards. Cuttings from each item were treated and extracted onto a microscope slide, dried, and stained using the Christmas Tree dyes, and examined microscopically.

Twenty-one out of 24 “source” fabrics tested positive for acid phosphatase and 20 out of 24 “source” fabrics tested positive for p30 protein. Fifteen out of 24 “source” items had visual fluorescent stains under an ALS. None of the “receiving” fabric items fluoresced under the ALS and none tested positive for AP or p30 protein. For the “receiving” items air dried for 24 hours prior to washing with a “source” item, 29 were negative for sperm while the remaining 19 had sperm counts ranging from 1 to 50+; with an average of 6.5 sperm/item. For the “receiving” items air dried for seven days prior to washing with a “source” item, 23 were negative for sperm while the remaining 25 had sperm counts ranging from 1 to 31, with an average of 5.6 sperm/item.

Cuttings from each “source” and “receiving” item were tested for DNA using polymerase chain reaction techniques. Twenty-two out of 24 “source” items provided full profiles consistent with the donors. One “receiving” sheet and two “receiving” towels provided full profiles consistent with the donors. Three “receiving” sheets, eight “receiving” panties, and three “receiving” towels provided information at a minimum of six loci, providing partial profiles in which the donors could not be excluded. All samples were extracted using a QIAGEN® EZ1® and quantified using Plexor® HY on an AB 7500®. Following the quantitation results, all of the samples were amplified using Identifiler® on an AB 9700®, and capillary electrophoresis was performed using an AB 3130xl.

In this study, sperm heads were visualized on the “receiving” items, demonstrating that transfer of spermatozoa during the laundering process can occur. This is important information to be aware of for investigators and laboratory scientists. Additional work is needed to develop enhanced evidence-collection guidelines. The results of future testing will help define laboratory sampling protocols and data interpretation procedures.

Sperm, Transfer, Washing Machine

B127 High-Resolution Melt Analysis of DNA Methylation Status as a Novel Method for Human Semen Identification

Caitlyn Deppen*, 77 Lodi Hill Road, Upper Black Eddy, PA 18972; and K. Joy Karnas, PhD, Cedar Crest College, 100 College Drive, Allentown, PA 18104

After attending this presentation, attendees will understand how DNA methylation patterns differ between cell types and how high-resolution melt curve analysis can be used in conjunction with bisulfite conversion to identify fluids based on their methylation status.

This presentation will impact the forensic science community by introducing a new method for semen identification that is based on DNA methylation and relies on instrumentation that is affordable and currently found in forensic laboratories. The method also offers the potential of being extended to multiple body fluid types.

Identification of the body fluid origin of a biological stain found at a crime scene can shed light on events that may have occurred. Unfortunately, current methods of body fluid identification rely on techniques that are subject to both false positives, through cross-reactivity between multiple fluids, or false negatives, due to protein degradation in the fluid. A recent study shows that it is possible to distinguish body fluids by examining the differentially methylated DNA in the fluid by pyrosequencing.¹ The location of methyl groups on DNA is known to regulate gene expression, and is thus tissue specific. It is also thought to be stable over long periods of time in deposited stains; however, pyrosequencing is a fairly new technique that is time-consuming and uses expensive equipment that is not currently available in most forensic laboratories.

The goal of this study was to develop a cost- and time-effective technique for the identification of body fluids by DNA methylation, using instrumentation typically available in crime laboratories.

Six blood, five saliva, four urine, and four vaginal fluid samples were obtained from 11 volunteers and five semen samples were obtained from different donors in a conical vial by self-collection. All semen samples were then deposited (5 μ L) on sterile cotton-tipped swabs. Bloodstains from 1998, 2003, and 2010 were also obtained and used to assess the stability of methylation over longer periods of time.

DNA was isolated from each swab using either organic extraction (saliva, urine, and vaginal fluid) or Chelex[®] 100 extraction (blood and semen) and subjected to bisulfite modification using a Zymo Research EZ DNA Methylation-Gold[™] kit, to convert unmethylated cytosines to uracil. The Qiagen[®] Epiect[®] High Resolution Melt (HRM) PCR Kit was used for melt curve analysis of amplicons containing known sites of differential methylation.^{2,3} Primers used in this kit are proprietary.

All body fluid stains were analyzed in triplicate. Results indicate that semen can be identified using post-amplification melting temperature differences compared to the other fluids used. This shift in melt temperature was found to be statistically significant for all five body fluids using a one-way Analysis of Variance (ANOVA) with a 95% confidence interval ($p=6.34 \times 10^{-5}$), as was expected for genes actively transcribed in tissue samples due to the lack of methyl groups, and thus bisulfite conversion of cytosine residues; however, when semen was removed from the statistical analysis, the remaining body fluids were found not to be statistically different from each other (one-way ANOVA at 95% confidence interval, $p=0.141$). Extraction and analysis of DNA from the 1998 blood case sample resulted in a melting temperature consistent with blood samples from volunteers indicating that the age of the stain does not affect this analysis. The results from case samples 2003 and 2010 yielded insufficient results. This method is also short tandem repeat-typing compatible due to DNA extraction prior to methylation analysis. Although only semen could be identified with this study, there are other potential primer sites that could help identify the other body fluids using the same method. This study does show that body fluid identification is possible for both old and fresh samples using DNA methylation and HRM analysis.

DNA Methylation, Melt Curve Analysis, Semen Identification

B128 Persistence of Sperm: What the Literature Really Says

James M. DiFrancesco, MFS, USACIL, 4930 N 31st Street, Bldg 925, Forest Park, GA 30297-5205; Elizabeth Richards, PhD, Defense Forensic Science Center, 4930 N 31st Street, Bldg 925, Forest Park, GA 30297; and Deborah K. Haller, BS, 2335 Village Green Drive, Fairburn, GA 30213*

The goal of this presentation is to shed light on the inconsistencies in the forensic literature regarding the persistence of spermatozoa in the vaginal cavity and cervix. Specifically, this presentation will show that the literature citations of spermatozoa persisting for 17 and 19 days are not reliable. This presentation will leave attendees more aware of how to critically read and process scientific literature.

This presentation will impact the forensic science community by increasing awareness of how journal articles are cited in the literature and the potential pitfalls in relying on secondary sources for setting laboratory and investigative policies and guidelines.

During the investigation of an alleged sexual offense, the timely recovery of physical evidence is crucial; however, for a variety of reasons, a victim of sexual assault may not report the alleged incident immediately. It is in these extended intervals between the alleged offense and reporting (post-assault interval), that key decisions must be made by investigators and laboratory examiners regarding if any physical evidence may still exist and how that evidence can best be recovered. The identification of semen can be of great importance in establishing sexual contact between an alleged victim and subject. It is the recovery of semen from the female victim that is frequently the focus of the investigative decision making efforts. The literature can give a misleading picture as to how long semen can be recovered from body cavity swabs taken during a sexual assault exam. Based on the scientific literature review, most of the citations state that spermatozoa can be detected approximately three days in the vaginal cavity and five to seven days in the cervix; however, there are a small number of published accounts relating that spermatozoa can be detected much later than a week in the vaginal cavity. These outliers in the literature can cause confusion as to when reliable semen results can be obtained from swabs collected during a sexual assault exam and identified during laboratory testing.

A literature review was performed to determine the veracity of two separate claims that spermatozoa can be recovered from the vaginal cavity up to 17 and 19 days post coitus. The specific source that cites a 17-day claim was traced to an article written in Italy in 1891. In that reference, the author was focused on artificial impregnation and fertilization. Based on the success of fertilization, the author determined spermatozoa may remain alive for as long as 17 days. The sources that reference this paper illustrate this claim is dubious at best. The claim of finding spermatozoa 19 days post coitus was traced to a conference abstract from 1977 that referred to data which was eventually published; however, the published paper did not address the 19-day findings stated in the conference proceedings. The data referenced in the conference proceedings was based upon self-reporting by female volunteers. In this case, the 19-day findings were regarded as “possibly correct” because very few spermatozoa were routinely observed after day ten. In the same reference, the authors noted that the reported post-coitus times of one month to many months where spermatozoa were found were incorrect because there were a high number of spermatozoa detected that did not show degenerative changes that would be expected. Even though these outliers are mentioned in these two papers, the preponderance of the data in these citations and others support the trend that spermatozoa can be detected three days in the vagina and up to seven days in the cervix post coitus.

During the laboratory’s search of the literature, these two outliers were found to be cited several times in an effort to illustrate that semen can persist outside of the traditionally expected time frame of three to seven days post coitus. The problem is the original sources that mention these figures are typically not cited directly in the literature. Instead, the literature articles cite various secondary sources to illustrate these claims. This made it very difficult to determine the origin of the data. Having knowledge of what the original sources of these claims say about the persistence of sperm has made it possible to educate submitters about the likelihood of obtaining usable data from samples collected 17 and 19 days post coitus.

Sperm, Persistence, Semen

B129 Persistence of DNA: A Case File Review

Deborah K. Haller, BS, U.S. Army Criminal Investigation Lab, 4930 N 31st Street, Forest Park, GA 30297; Diana Fleming, MFS*, AFOSI 1 FIS, 721 Vandenberg Drive, Travis AFB, CA 94535; Elizabeth Richards, PhD, Defense Forensic Science Center, 4930 N 31st Street, Bldg 925, Forest Park, GA 30297; James M. DiFrancesco, MFS, USACIL, 4930 N 31st Street, Bldg 925, Forest Park, GA 30297-5205; and Molly Hall, BS, U.S. Army Criminal Investigation Lab, 4930 N 31st Street, Forest Park, GA 30297*

The goal of this presentation is to educate attendees on how long semen and DNA persist on casework samples collected during a sexual assault exam from or using actual casework data.

This presentation will impact the forensic science community by increasing awareness of how long semen can persist on samples collected during a Sexual Assault Nurse Exam (SANE) and the impact of time on the ability to recover DNA using standard DNA techniques that are currently utilized at the United States Army Criminal Investigation Laboratory (USACIL).

During the investigation of an alleged sexual offense, the timely recovery of physical evidence is crucial; however, for a variety of reasons, a victim of sexual assault may not report the alleged incident immediately. It is in these extended intervals between the alleged offense and reporting (i.e., the post-assault interval) that key decisions must be made by investigators and laboratory examiners regarding if any physical evidence may still exist and how that evidence can best be recovered and subsequently tested. Identifying semen and obtaining a DNA profile are not synonymous. The identification of semen can be of great importance in establishing sexual contact between an alleged victim and subject. It is the recovery of semen from the female victim that is frequently the focus of the investigative decision-making efforts. Though there is literature on the subject of semen and DNA persistence in the vagina and cervix, the sensitivity and availability of the techniques used to detect semen and DNA vary from laboratory to laboratory. In an effort to give more accurate guidelines to SANEs who collect the evidence and to federal agents who submit evidence to the USACIL, past case files were reviewed in order to determine a realistic time frame in which semen and DNA can be recovered.

A search of the USACIL DNA casework files from 2012 to 2014 from all branches of the military was performed in order to determine the time frame of obtaining serology results and DNA profiles from post-coital swabs taken from casework samples. In addition, this review also included the amount of DNA obtained from different types of body swabs in relation to the post-assault activity and interval, a tally of the number of sexual assault submissions without a Sexual Assault Evidence Collection Kit (SAECK), and the reason such a kit was not obtained.

In conjunction with the review of the USACIL cases, a review of United States Air Force (USAF) cases was also performed. This review focused on sexual assault cases reported to and investigated by the Air Force Office of Special Investigations (AFOSI) during calendar year 2013. The AFOSI review focused on the following contextual data: (1) the average time between the alleged assault and obtaining a SAECK; (2) the number of cases where no SAECK was obtained and why; (3) the number of cases where a SAECK was collected and submitted to the USACIL for analysis; (4) the number of cases where a SAECK was collected but not submitted to the USACIL for analysis and why; (5) the number cases where a SAECK was submitted to the USACIL but not processed and why; and, (6) the outcome of the cases. The time between alleged incident and collection, serology and DNA results for body cavity swabs, the number of sexual assault cases submitted without a kit, and the reason that a kit wasn't collected was recorded and tallied.

The data collected is important for providing a sound basis for guidelines used by the laboratory and the USAF regarding the submission and testing of SAECKs that are collected in the field.

The opinions or assertions contained herein are the private views of the author and are not to be construed as official or as reflecting the views of the Department of the Army or the Department of Defense.

Semen, Persistence, DNA

B130 Intra-Bone Variation of Recoverable Nuclear and Mitochondrial DNA in Femora

*Timothy C. Antinick, BA**, Michigan State University, 560 Baker Hall, East Lansing, MI 48824; and *David R. Foran, PhD*, Michigan State University, Forensic Science Program, 560 Baker Hall, East Lansing, MI 48824

After attending this presentation, attendees will learn: (1) that DNA content varies significantly along the length of the femur; (2) the implications this has on recovering nuclear and mitochondrial DNA from skeletal remains; and, (3) practical recommendations for improving DNA recovery from femoral tissue.

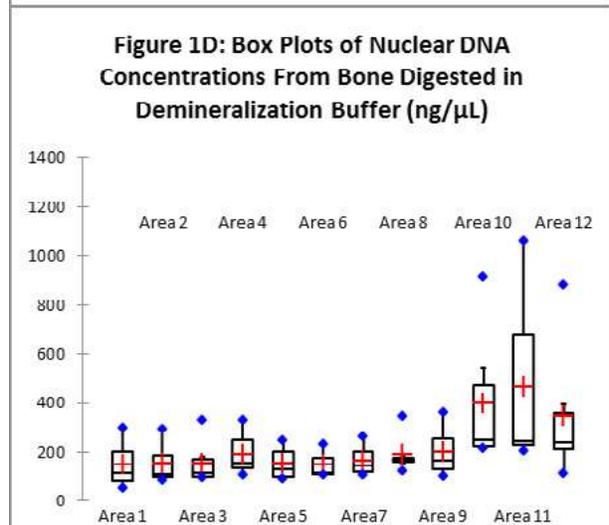

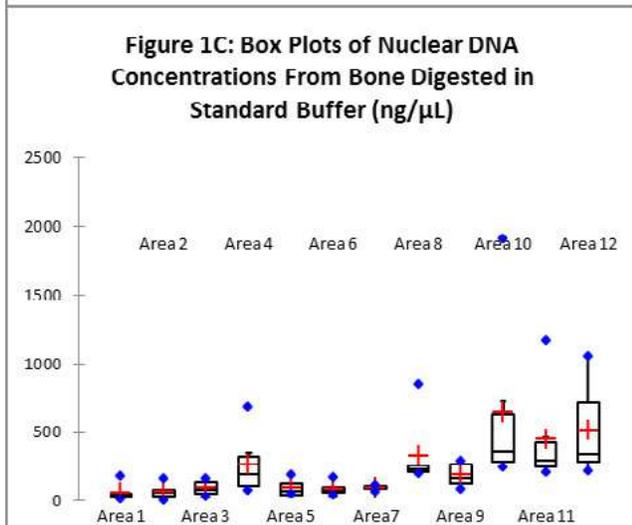

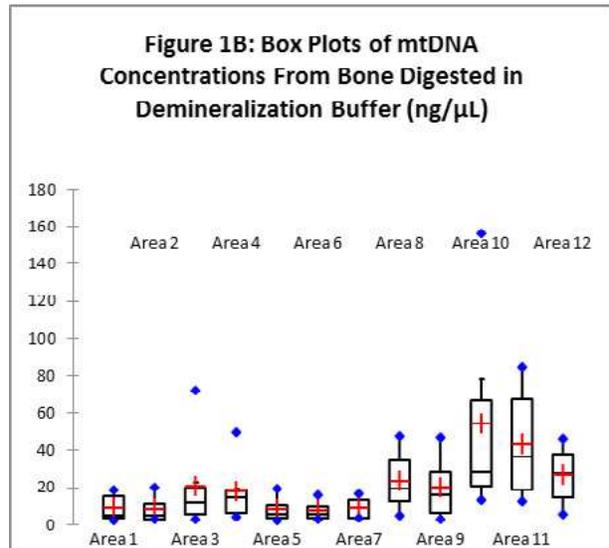

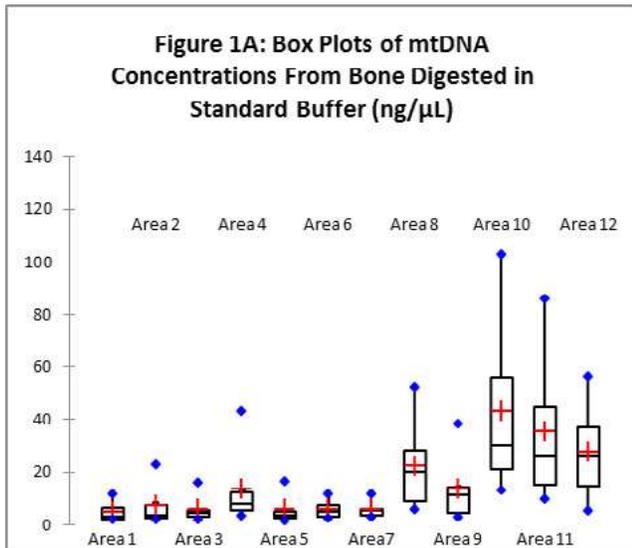

This presentation will impact the forensic science community by informing practitioners about intra-bone variation of recoverable DNA from femora. Further, these findings could have immediate impact for practitioners by improving sampling strategies, increasing first-pass success rates of generating a DNA profile, and saving forensic laboratories time, money, and resources.

Positive identification of skeletal remains is not always possible owing to a lack of antemortem records, their level of preservation, or the remains being substantially incomplete or fragmented. Identification in these instances frequently relies on obtaining DNA from skeletal material. Research and practice have shown that successfully recovering DNA from bone is based upon several factors, including environmental conditions, extraction methodology, and different bones of the body.¹⁻³ Further, cortical osseous tissue from weight-bearing long bones (e.g., the femur and tibia) tends to be a better target for obtaining amplifiable DNA than trabecular bone and because midshaft diaphysis of the femur and tibia contain an abundance of cortical bone, they have become a preferential target for DNA extraction; however, there is currently a lack of research on intra-bone DNA variation.^{1,4} As an example, the femur, with its large size, surface area, and varied distribution of osseous tissue types, has the potential to contain a wide array of DNA variability.

In this research, fresh bovine femora were first macerated in a boiling 1% Terg-a-zyme[®] solution to remove soft tissues. Twelve regions of the femur, including eight equidistant sections of diaphysis extending proximally and distally from the midshaft as well as the proximal and distal epiphyses were drilled using a Dremel[®] tool with a 7/64-inch cobalt drill bit. Bone powder from each region was divided between two digestion methods: standard laboratory digestion buffer (20mM Tris, — pH 7.5; 50mM EDTA; 0.1% SDS) or demineralization buffer (0.5 M EDTA — pH 8.0; 1% Laural-Sarcosinate), extracted organically, and concentrated using Amicon[®] filtration columns. DNA quantification of extracts utilized a TaqMan[®] real-time polymerase chain reaction assay targeting the nuclear MC1R and mitochondrial ATPase8 loci. To determine quality, DNAs were amplified utilizing a series of primer sets that generated ~200, 400, 600, and 1,000 base pair amplicons. All results were examined statistically at an α of 0.05 utilizing analysis of variance in conjunction with post-hoc pairwise comparisons to determine areas of significant difference.

Resulting data (Figures 1A–D) showed substantial variation in DNA yields across femoral regions. Significantly more nuclear and mitochondrial DNA was obtained from the distal and proximal femoral epiphyses than the diaphysis. Areas of diaphysis close to the epiphyses, as well as auricular surfaces, had more DNA than midshaft diaphysis, which consistently had the lowest amount of recoverable DNA. The mitochondrial (1,000 base pairs) and nuclear (400 base pairs) DNA amplicons were consistently generated from all regions of the femur; however, larger nuclear DNA amplicons (600 and 1,000 base pairs) were inconsistently obtained across the femur.

These findings indicate that substantial variation in DNA levels exists along the femur. Furthermore, midshaft femur, commonly sampled by forensic practitioners, appears to be suboptimal for obtaining recoverable nuclear and mitochondrial DNA. Given the value of DNA in establishing the identity of skeletal remains and the common use of weight-bearing long bones such as the femur for obtaining that DNA, this research has the potential to be of considerable utility to forensic laboratories, and thus, to the criminal justice system.

DNA Quality and Quantity, Skeletal Variation, DNA Recovery

B131 Effect of Skeletal Sampling Technique on DNA and Elemental Analysis Results

Laura Gaydosh Combs, MA*, UNT Health Science Center, Forensic & Investigative Genetics, 3500 Camp Bowie Boulevard CBH-355, Fort Worth, TX 76107; Vivian Huynh, BS, University of North Texas (Denton), 1201 N Austin Street, Apt 1, Denton, TX 76201; Teresa D. Golden, PhD, University of North Texas, Dept of Chemistry, 1155 Union Circle, #305070, Denton, TX 76203; Joseph E. Warren, PhD, 3500 Camp Bowie Boulevard, Fort Worth, TX 76107; and Rhonda K. Roby, PhD, J. Craig Venter Institute/Human Longevity, Inc, 4120 Capricorn Lane, San Diego, CA 92037

After attending this presentation, attendees will understand the relationship between skeletal sampling technique and recovery of nucleic acids and elemental materials and the reduction in the quality of Short Tandem Repeat (STR) results due to DNA damage from laboratory processing and Polymerase Chain Reaction (PCR) inhibition from co-isolated elements.

This presentation will impact the forensic science community by demonstrating the effect of skeletal sampling technique on the DNA recovered and mineral constituents co-isolated from DNA extraction of human skeletal remains. Presented data include measurement of DNA quality and quantity, genetic analyses, and determination of elemental contents.

The goal supported by this work is to identify more people from skeletal remains by developing improved procedures for extracting DNA from bone samples. Bones are considered one of the most challenging sample types due to laborious laboratory processing that may result in incomplete genetic results or amplification failure. Causes of poor results may include DNA damage, inhibition of PCR, and/or inefficient extraction. These experiments will determine whether skeletal sampling technique contributes to poor quality DNA analysis results and resulting data will provide a foundation for the development of improved procedures to extract DNA from skeletal remains.

Cadaver long bones were obtained through the Willed Body Program at the University of North Texas (UNT) Health Science Center and samples were cut from the diaphysis of a left tibia. Three extraction sets, each comprised of five samples and a reagent blank, were tested for DNA and elemental contents. The three sets included the following: whole bone pieces weighing between 0.837 and 0.935 gram, numerous bone cuttings with a total sample weight between 0.887 and 0.915 gram, and pulverized samples weighing between 0.905 and 0.912 gram. DNA extraction was performed using the UNT Center for Human Identification "Demineralization Extraction of Skeletal Remains" protocol, a modified version of the Loreille et al. method.¹ Samples were weighed and placed into tubes. Demineralization buffer and proteinase K were added to each sample and incubated overnight. An equal volume of Phenol-Chloroform-Isoamyl Alcohol (PCIA) was added and samples were vortexed and centrifuged. A 1mL aliquot was removed from the aqueous phase for ethanol purification and subsequent testing and the remaining aqueous phase was transferred to a centrifugal filtration device. Samples were centrifuged through the device and the retentate was purified using a chaotropic salt solution and a centrifugation column.

Two fractions were examined: the aqueous phase following PCIA purification, subsequently purified with ethanol; and the fully purified samples, consisting of the retentate from the centrifugal filtration and purified using a second column. Contents of the aqueous phase formed crystals as a result of ethanol purification. These samples were dissolved in TE⁻⁴ buffer and the DNA content evaluated using a microfluidic platform. The crystals were again formed with ethanol and examined by X-ray diffraction. Fully-purified samples were tested for DNA content using the following methods: sizing on a microfluidic platform in duplicate; two qPCR DNA quantification kits in triplicate; STR amplification in triplicate; and, genetic analysis on two models of capillary electrophoresis instruments. Elemental analysis of both fractions was performed using Inductively Coupled Plasma/Mass Spectrometry (ICP/MS). Baseline and subsequent analyses were performed in solution mode ICP/MS. Acid digestion was used for baseline sample preparation; approximately 100mg of sample was dissolved in concentrated nitric acid (HNO₃), and then diluted with 1% HNO₃. Dilution factors varied between 20 and 100 for aluminum, calcium, copper, iron, nickel, and lead. All samples were measured in triplicate.

Results were successfully obtained for each assay attempted. DNA quantification yields for pulverized bone were 16.7 to 93.3 times higher than whole or cut bone pieces; however, STR profiles obtained for the cut bone pieces were superior to whole or pulverized bone samples. STR profile quality was assessed by determining the percent of fluorescence exhibited by the highest molecular weight allele versus the lowest molecular weight allele for a dye channel. The range of percent recovery of the highest molecular weight allele for whole bone was 1.72% to 35.66%, cut bone was 4.82% to 49.79%, and pulverized bone was 0.96% to 18.05%.

Skeletal Remains, DNA Extraction, Elemental Analysis

B132 Development of a Multiplex Quantitative PCR (qPCR) Assay for Simultaneous Quantification of Human Nuclear and Mitochondrial DNA From Forensically Relevant Samples

Brittania J. Bintz, MSc, 111 Memorial Drive, NSB 231, Cullowhee, NC 28723; and Mark R. Wilson, PhD, Western Carolina University, Dept of Chemistry/Physics, Forensic Science, Cullowhee, NC 28723*

After attending this presentation, attendees will have a better understanding of ongoing efforts to develop a multiplex quantitative Polymerase Chain Reaction (qPCR) assay that enables simultaneous quantification of human nuclear and mitochondrial DNA (mtDNA). Additionally, principles of droplet digital PCR (ddPCR), a newly emerging quantitative technique, will be presented.

This presentation will impact the forensic science community by providing a method for comprehensive quantitative analysis of DNA in forensically relevant samples.

In forensic casework, multilocus Short Tandem Repeat (STR) typing is often the preferred method of analysis due to its high power of discrimination however, many evidentiary samples contain low amounts of DNA or degraded DNA that is not suitable for STR typing. In these cases, mtDNA sequence analysis is typically performed. Determining which investigative approach is most suitable can be challenging, especially in cases where the sample or extract is limited. Here, a powerful multiplex 5' nuclease real-time PCR assay is described that enables simultaneous quantification of both human nuclear and mitochondrial DNA from a sample extract. This tool provides specific quantitative data that can be used to determine the most appropriate analytical workflow without consumption of additional sample or increase in labor compared to methods currently used in crime laboratories.

The nuclear target for this custom qPCR assay is the 275bp Alu Yd6 mobile element originally described by Xing et al.¹ High sensitivity of nuclear DNA quantitation using the multicopy Alu Yd6 marker has previously been reported and a qPCR assay designed for this target has been used successfully.^{2,3} The mtDNA target sequence corresponds to a 105bp segment of the NADH dehydrogenase subunit 5 gene and is described by Kavlick et. al. for use in an assay that is utilized routinely in several forensic laboratories.⁴ Both targets have been shown to exhibit little to no cross-reactivity with non-human sources.^{2,4} In addition to these primary targets, an Internal Positive Control (IPC) has also been included for assessment of possible PCR inhibition.

Initially, 2800M human control DNA was characterized using ddPCR for use as a qPCR standard. This absolute quantitative technique enables accurate and precise quantitation of nucleic acids. Briefly, a 20 μ L sample containing TaqMan[®] PCR reagents and sample DNA extract is partitioned into approximately 20,000nL-sized droplets. The droplets then act as independent microreactors where fluorescent reporter dyes are liberated from target specific probes during PCR. Following PCR, the droplets are counted as target positive or negative depending on the presence or absence of fluorescence detected by a droplet reader. Target concentrations are estimated by software using a Poisson model. Human nuclear and mtDNA in control sample 2800M were separately quantified in singleplex ddPCR reactions. This data was then used to prepare a single standard dilution series of 2800M DNA with quantitative ranges of 10ng/ μ L to 1fg/ μ L of nuclear DNA and 400,000 copies/ μ L to 0.04 copies/ μ L of mtDNA. Each qPCR quantitation was performed both as a duplex assay (primary target and IPC together) and as a multiplex assay (both primary targets and IPC together). Resulting PCR efficiencies and sample quantitations were compared. Preliminary data suggests that multiplexing has a minimal derogatory effect on the efficiency of each assay and, as a result, sample quantitations are similar when using singleplex or multiplex qPCR.

The assay described herein offers a high degree of specificity and sensitivity and facilitates preservation of limited samples while allowing the analyst to determine the optimum analytical approach for each sample. In the future, a larger target of the mtGenome will also be included in the multiplex assay to enable assessment of DNA degradation.

Eisenberg, PhD*, UNT Health Science Center at Fort Worth, 3500 Camp Bowie Boulevard, Fort Worth, TX 76107

After attending this presentation, attendees will understand the application of a novel DNA marker system for use with missing persons samples.

This presentation will impact the forensic science community by serving as a key aspect for the analysis of degraded forensic DNA samples, as it can augment or replace traditional DNA testing systems in cases where those systems do not produce results due to the presence of highly degraded DNA.

The Missing Persons unit of the UNT Center for Human ID (UNTCHI) annually processes more than 2,600 specimens including human remains, family reference samples, and direct reference samples. The ability to successfully type these human remains samples using DNA analysis is of utmost importance for their identification. In these cases, identification is achieved primarily through Short Tandem Repeat (STR), Y-chromosomal Short Tandem Repeat (Y-STR), and mitochondrial DNA analyses; however, this approach is often restricted by common haplotypes and the excessively degraded condition of samples, thereby limiting the discrimination power of DNA using these technologies. To address these limitations, the UNTCHI strives to optimize and validate new techniques to assist with the identifications in missing persons cases. This presentation focuses on the utilization of a novel DNA marker system, for use with the types of samples commonly encountered in the Missing Persons unit at UNTCHI.

InnoTyper™ is a marker system that utilizes Retrotransposon Insertion Polymorphisms (RIPs). Retrotransposable Elements (REs) consist of Long Interspersed Nuclear Elements (LINEs) and Short Interspersed Nuclear Elements (SINEs). This group of bi-allelic markers can be useful for human identity testing. Among the advantages of using RIPs are that they do not yield stutter artifacts due to slippage during the PCR, there are no known genetic mutations since they are identical by descent only, they are present in very high copy numbers, and they have a well-defined genetic lineage, which makes RIPs useful for relationship determinations; however, until recently due to the inherent size difference (>300bp) associated with insertion and null alleles, the use of RIPs has not been practical for forensic applications. To circumvent the allele size disparity, a novel primer design methodology was used to remove the intra-specific locus competition that occurs in heterozygotes. This innovative primer design allows for the amplicon size to be reduced to a size smaller than currently used STR markers, such that substantially degraded DNA samples can be analyzed. Utilizing this primer design, a more simplified, rapid, and automated typing technology can be applied to RIP typing.

The multiplex utilized in this study consisted of 13 RE markers plus the gender identifying marker, amelogenin. All amplicons in this PCR multiplex range in size between 50bp to 125bp. To test the utility of this system in a forensic casework missing persons laboratory, several studies were performed, including sensitivity and testing on non-probative human remains. Results show the system to be highly robust and sensitive. Complete 13 RE marker profiles were obtained with as little as 16pg. These results were compared to the low copy procedure used by UNTCHI. The small amplicon sizes result in an extremely sensitive, rapid, and useful multiplex for typing highly degraded forensic samples as well as for high-quality DNA samples.

Data to be presented supports the usefulness of this system for analyzing missing persons samples which did not produce usable STR results but did provide InnoTyper™ results with high discrimination power. This system will prove very useful for analyzing single-source degraded DNA samples such as those found in mass disasters and other human identification efforts.

DNA, Degradation, Retrotransposon

B134 Hair and Calcified Tissue DNA Extracts: qPCR-Based Guidelines/Strategies for Streamlined Mitochondrial DNA (mtDNA) Amplification and Improved mtDNA Sequence Recovery

*Michael D. Brandhagen, PhD**, 2501 Investigation Parkway, Quantico, VA 22135; and *Jodi A. Irwin, PhD*, 2501 Investigation Parkway, Quantico, VA 22135

After attending this presentation, attendees will better understand how mtDNA quantitative Polymerase Chain Reaction (qPCR) values can be used to increase sequence data recovery and minimize sample consumption.

This presentation will impact the forensic science community by providing practical, data-driven mtDNA-processing guidelines for streamlined mtDNA workflows.

Mitochondrial DNA (mtDNA) is a valuable forensic marker for samples such as hair and calcified tissue, as they routinely fail upon nuclear DNA (nDNA) analysis due to DNA degradation or insufficient template. Though mtDNA can generally be recovered from these sample types, the mtDNA content is often still quite limited and the source material is almost always limited. Under these circumstances, a mechanism for determining the most efficient and successful amplification strategy would lead to reduced sample consumption and an increase in the quantity of sequence information obtained.

The mtDNA Control Region (CR, rCRS 15998-616) is routinely targeted for analysis due to its high inter-individual variation. Historically, CR data have been recovered at the Federal Bureau of Investigation (FBI) laboratory with four amplicons (designated HV1A, HV1B, HV2A, HV2B, each ~230bp to 290bp) that sit within mtDNA Hypervariable Region 1 (HV1, rCRS 15998-16390) or Hypervariable Region 2 (HV2, rCRS 49-408). Though amplification of smaller fragments is also often performed, previous studies and two decades of casework experience have shown that larger fragments are seldom recoverable. As a result, they are rarely targeted for amplification.

With the recent implementation of new extraction procedures for calcified tissues and hairs, a dramatic improvement in the quantity/quality of mtDNA recovered from these specimen types has been observed. Studies have shown a 2- to 30-fold increase in mtDNA copy number (as determined by a custom real-time quantitative PCR (qPCR)) and established that fragments >350bp are now recoverable.¹ In addition, results show that the qPCR values, though based on a 105bp amplicon, provide an indication of CR amplification success with amplicons of varying size. Not surprisingly, extracts with greater qPCR values tend to produce amplicons of greater size.

In order to further define the mtDNA quantities required for successful amplification and develop practical guidelines for casework implementation, representative extracts were quantified by qPCR and then amplified with primer sets targeting CR fragments of various size. Amplicons ranging from ~230bp to 1,100bp (the entire CR) were tested, then extracts producing successful amplification were evaluated for their corresponding mtDNA quantities. Minimum mtDNA quantities required to produce successful amplification at a given fragment size were conservatively established based on the highest quanting extracts (75%) that led to amplification product. Based on this criterion, guidelines were established to amplify entire HV1 and HV2 region amplicons (~360bp to 390bp) from hair extracts when $\geq 1,500$ copies/ μ L are detected (100% successful in studies) and entire CR with values $\geq 8,000$ copies/ μ L (95% successful in studies). Similarly, for calcified tissue, the entire CR can be amplified with values $\geq 30,000$ copies/ μ L (85% successful in casework and studies) and HV1 and HV2 can be targeted with as little as 400 copies/ μ L (100% successful in casework and studies). As a result of these guidelines, approximately 60% and 85% of calcified tissue and hair cases, respectively, have successfully yielded HVI and HVII amplicons. Moreover, the entire control region (~1100bp) has been successfully amplified from casework hair and calcified tissue specimens, whereas previously this would have not even been attempted.

The guidelines are continually being updated with casework data to maintain the most efficient and successful use of DNA extracts for current mtDNA analyses. In addition, it is expected that qPCR-based guidelines may be similarly useful with forthcoming Next Generation Sequencing (NGS) assays and applications. In fact, recent experiments have shown that 2kb to 3kb fragments spanning the entire mtGenome can be recovered from some hair samples with values of $\geq 30,000$ copies/ μ L and that these amplicons can be successfully sequenced using the Nextera[®] XT DNA Sample Preparation Kit and the Illumina MiSeq[™].

For poor quality evidentiary material containing damaged and/or low quantities of DNA, knowledge of the amplifiable mtDNA content has led to more informed casework decisions on downstream PCR. This in turn has led to decreased sample processing time and cost, more judicious use of limited sample material, and, most importantly, more successful mtDNA testing outcomes.

B135 Recovering Touch DNA From Cartridge Casings Using a Method of Tape Lifting

Ting Chi Rebecca Wan, BS, 2400 Virginia Avenue, NW, #C626, Washington, DC 20037; Lauren MacDonald, 1101 New Hampshire Avenue, Unit 509, Washington, DC 20037; Yoelia Perez, BS, 3636 16th Street, NW, Apt BG-04, Washington, DC 20010; Todd W. Bille, MS, Bureau of ATFE, National Laboratory Center, 6000 Ammendale Road, Ammendale, MD 20705; and Daniele S. Podini, PhD, Department of Forensic Science, 2100 Foxhall Road, NW, Washington, DC 20007*

After attending this presentation, attendees will better understand a more effective method to recover DNA from unfired cartridge casings compared to conventional wet-swabbing techniques.

This presentation will impact the forensic science community by providing a more effective process for recovering DNA from copper and copper-alloy surfaces.

Previous studies suggested that copper-induced degradation significantly lowered the amount of DNA recovered when copper or copper alloys were wet-swabbed. This phenomenon will reduce the recovery of epithelial cells and Cell-free Nucleic Acids (CNAs) deposited on the surface of a casing when loading a gun. To overcome this issue, tape-lifting was evaluated as a method to remove cells from the surface of cartridge casings.

In this experiment, the method of tape-lifting was used to recover touch DNA from unfired brass and nickel casings. Tape-lifting prevents any interaction between the copper component of brass and the aqueous solutions. Nickel casings were used as an experimental control. To evaluate the efficiency of the tape-lifting method, multiple individuals were asked to deposit touch DNA on cleaned brass and nickel cartridge casings. Four experiments were performed. Three donors participated in all four experiments, while three other donors participated in one experiment each. The donors were asked to roll a single casing in each hand for one minute, switching the casings from hand to hand every 15 seconds in order to try to equalize the amount of touch DNA on each casing. The DNA was allowed to stand on the casings for 48 hours before collection and extraction. In cases where donors needed to provide touch DNA on more than two casings for the experiment, the second set of casings were made available to the donors one hour after their first donation in order to maximize cell shedding between donations. The DNA was collected from the casings using both wet-swabbing and tape-lifting methods for comparison. DNA extraction was performed using Qiagen® QiaAMP® DNA Investigator® Kit. Quantitation was performed using an in house TaqMan® assay targeting autosomal DNA plus an internal control for inhibition developed for the Cepheid® SmartCycler® automated real-time PCR system.

Experimental results showed that the tape-lifting method recovered significantly more DNA than the wet-swabbing method from the brass cartridge casings, while no significant difference was observed between the two methods on nickel casings. Even though the amount of DNA recovered from brass cartridge casings was improved with the tape-lifting method, it was still significantly lower than the amount of DNA extracted using tape from nickel cartridge casings. Therefore, with the overall amount of DNA recovered from nickel being higher than that recovered from brass, the results suggest that degradation still occurs even without an aqueous medium. The average amounts of total DNA collected and extracted from brass using the swabbing and tape-lifting methods were 0.03181ng±0.03905ng, and 0.09965ng±0.06456ng, respectively. The average amounts of total DNA collected and extracted from nickel using the swabbing and tape-lifting methods were 0.16060ng±0.15795ng and 0.19068ng±0.15276ng, respectively. The above calculations were based on interim results of nine replicates of brass casings and seven replicates of nickel casings for both swabbing and tape-lifting methods. To confirm sample source, STR amplification was performed using AmpFISTR® Identifiler® Plus and analyzed on an ABI® Prism 3130® Genetic Analyzer. Although STR analysis yielded partial profiles in most cases, the lowest being 2/16 loci, the highest being 16/16 loci, and the average being 9.5/16 loci, the DNA recovered from the sampled surface matched the appropriate donor.

Touch DNA, Tape Lifting, Cartridge Casings

B136 Evaluation and Optimization of DNA Recovery From Bullet Cartridge Cases

Meghan Troy, MSFS*, 2300 Stratford Avenue, Willow Grove, PA 19090; Christian G. Westring, PhD, 2300 Stratford Avenue, Willow Grove, PA 19090; Phillip Danielson, PhD, Department of Biology, 2101 E Wesley Avenue, Lab 223, Denver, CO 80210; and Heather E. Mazzanti, MSFS, 450 S Easton Road, Glenside, PA 19038

After attending this presentation, attendees will be aware of optimized methods for the recovery of nuclear DNA from spent cartridge cases.

This presentation will impact the forensic science community by examining the ability forensic biologists have to obtain useful DNA profiles from cartridge cases through the evaluation and optimization of collection and extraction techniques.

Firearms were used in 69.3% of homicides, 41% of robberies, and 21.8% of aggravated assaults in the United States in 2012. Accordingly, both fired and unfired cartridge cases are commonly encountered at crime scenes; however, despite the prevalence of this sample type, DNA testing is not often sought as it frequently fails to produce an interpretable profile. A common explanation for this poor/minimal “touch type” DNA transfer to non-porous surfaces. Another explanation is possible damage to DNA by the heat generated during the firing process. This degradation would lead to preferential amplification of those loci with shorter base pair lengths and the loss of amplifiable alleles at larger loci. It has also been hypothesized that co-eluting reactive metal ion species from Gun Shot Residue (GSR) or from the cartridge case itself can result in either inhibition and/or the accelerated degradation of DNA.

In order to optimize DNA recovery, different collection and extraction techniques were evaluated with cartridge cases of various metal compositions. Two collection techniques, double-swab and sonication, were evaluated by sampling sixty .22LR caliber cartridge cases. Additionally, two extraction techniques, a robotic extraction technique utilizing Qiagen®’s EZ1® Advanced XL system and a manual phenol:chloroform extraction protocol, were assessed by sampling 200 .45 caliber rounds. All samples were quantified using real-time quantitative PCR with Life Technologies® Quantifiler® Human DNA Quantification kit, amplified using Promega’s® PowerPlex® 16HS amplification kit, and analyzed using an Applied Biosystems® 3130 Genetic Analyzer with ABI’s® GeneMapper® software.

It was determined that the use of sonication for collection along with a phenol:chloroform extraction method results in significantly greater DNA recovery than using a double-swab collection technique or a robotic extraction technique. Sonication recovered an average of 50% of DNA compared to an average 11% recovered with a double-swab technique. Although the robotic extraction technique produced more consistent results, the average DNA recovery was significantly lower as compared to the phenol:chloroform extraction method. The robotic extraction technique resulted in an average DNA recovery of 3.65pg/μL with a standard deviation of 1.9, while the phenol:chloroform extraction technique allowed an average DNA recovery of 7.65pg/μL with a standard deviation of 10.6.

In order to assess the role GSR has on observed differences in the recovery of DNA from the various extraction methods used, a suspension of GSR was created using internal barrel swabs of recently fired guns. Increasing volumes of this suspension (1μL, 5μL, 7.5μL, and 10μL) were added to eight samples of 2800M positive-control DNA. These samples were then extracted using either the EZ1® protocol or the phenol:chloroform protocol. The EZ1® extraction protocol resulted in DNA profiles with significant variability and poor inter-locus signal balance. Several of the samples extracted using the EZ1® protocol demonstrated preferential amplification or peak height suppression. Samples which were extracted using the phenol:chloroform protocol produced DNA profiles with consistently high and well-balanced allelic peaks across all loci.

In order to assess the role which the extraction method plays in samples from handguns, 18 swabs were prepared under controlled laboratory conditions from the slide serrations of handguns known to contain multiple contributors. Half of each sample was extracted using the robotic protocol and the remaining half was extracted with a phenol:chloroform protocol. The EZ1® extraction protocol resulted in DNA profiles with an average RFU value of 60. Samples which were extracted using the phenol:chloroform protocol produced full DNA profiles with an average RFU value of 2,000.

This research offers an optimized method for DNA recovery from cartridge cases and demonstrates that the adverse impacts on DNA profiles associated with samples originating from handguns could be due to the inability of commonly employed robotic extraction methods to remove co-eluting species which have been demonstrated to affect downstream analysis.

Cartridge Cases, STR Typing, Touch DNA

B137 Evaluation of a Vacuum-Swab Protocol for Recovering Epithelial Cells From Handled Evidentiary Samples

*Kevin J. Piccirilli, BS**, 651 Brooke Road, Apt E57, Glenside, PA 19038; *Britton L.F. Morin, MSFS*, 2300 Stratford Avenue, Willow Grove, PA 19090; *Jillian C. Fesolovich, MSFS*, 2300 Stratford Avenue, Willow Grove, PA 19090; and *Heather E. Mazzanti, MSFS*, 450 S Easton Road, Glenside, PA 19038

After attending this presentation, attendees will be able to implement a cost-effective and efficient collection technique for the recovery of epithelial cells from handled forensic samples.

This presentation will impact the forensic science community by introducing an efficient collection technique for the recovery of touch DNA from forensic samples. This vacuum-swab technique can easily be implemented into current forensic laboratories without the need of purchasing expensive equipment.

Handled evidence, such as clothing, firearms, and tools, are frequently submitted to forensic biology laboratories for Short Tandem Repeat (STR) typing. This has resulted in a growing need for a cost-effective and efficient collection technique for recovering biological material from handled items of evidence. Due to the limited quantities of DNA that can be left behind on handled objects, it is essential that the recovery method employed provides the maximum possible percent recovery of epithelial cells and therefore the greatest chance of generating a quality genetic profile. Current recovery techniques used to collect epithelial cells include the double-swab method, the tape-lift method, and the scraping method. On hard, non-porous surfaces, the double-swab technique has been shown to be the most effective. In a comparison using filter paper, single-swab, and double-swab techniques, the double-swab technique yielded the greatest quantity of DNA. The use of adhesive tape has been shown to be the most effective on porous samples, yet recovered only 55% or less of the donor's genetic profile. An additional collection method using a vacuum apparatus has been shown to produce promising results from porous items of evidence. This system sprays a buffer onto the surface of an item of evidence while simultaneously suctioning from the surface, thus collecting cellular material in a large volume of buffer; however, this necessitates the use of an additional filtration step to collect cellular material for DNA extraction. The current study evaluated these DNA recovery techniques in comparison to an alternative vacuum-swab technique to determine the optimum method of collecting epithelial cells from porous substrates.

Buccal cells were collected from a single donor and deposited on fabric at varying concentrations and allowed to dry. For the double-swab method, a swab moistened with 2% Sodium Dodecyl Sulfate (SDS) was first passed over the surface of the fabric ensuring maximum contact between the swab and surface. A second dry swab was then passed over the fabric and combined with the initial swab for extraction. For the tape-lift method, water-soluble tape was firmly pressed against the surface of the fabric and directly added to tubes for extraction. For the scraping method, a scalpel blade was passed over the fabric held at an angle to recover cellular material on the surface of the fabric. The vacuum-swab technique used a sterile glass tube with a cotton plug attached to a rough pump vacuum apparatus. All samples were quantified and then amplified at 16 polymorphic loci and analyzed using capillary electrophoresis. Quantitative values were compared for each method and resulting genetic profiles were assessed to ensure no allelic drop-in or sample contamination.

Equal volumes of liquid buccal cell slurry were extracted with samples that had the same volume deposited on fabric prior to collection. This was used to calculate a theoretical DNA quantity deposited on the fabric swatches and, therefore, the percent recovery of each collection protocol. Significant differences were found among the four methods of recovery ($p \leq 0.001$). The double-swab and scraping methods showed the poorest percent recovery, while the tape-lift and vacuum-swab methods showed the best percent recovery. At each concentration assessed, the tape-lift and vacuum-swab methods collected on average two to five times greater DNA concentrations, respectively. Amplification results demonstrated the absence of contamination in all cases. This data illustrate that the vacuum-swab and tape-lift collection protocols employed can enhance the quantity of recovered DNA from handled items and, therefore, are best suited for use in forensic biology laboratories for submitted porous evidence types.

STR Typing, Vacuum Swabbing, Touch DNA

B138 Evaluation of a Novel Approach to Low-Copy Number (LCN) DNA Methodologies for Generation of Short Tandem Repeat (STR) Profiles

Chandra Bagley, BS, 318 Oak Road, Glenside, PA 19038; Britton L.F. Morin, MSFS, 2300 Stratford Avenue, Willow Grove, PA 19090; Christian G. Westring, PhD, 2300 Stratford Avenue, Willow Grove, PA 19090; Phillip Danielson, PhD, Department of Biology, 2101 E Wesley Avenue, Lab 223, Denver, CO 80210; and Heather E. Mazzanti, MSFS, 450 S Easton Road, Glenside, PA 19038*

After attending this presentation, attendees will be familiar with the relative impact of different approaches to low-copy DNA analysis on stochastic effects as compared to increased Polymerase Chain Reaction (PCR) cycle number protocols.

This presentation will impact the forensic science community by assessing alternative methods for analyzing low template DNA from evidentiary material that will allow for the generation of more complete STR profiles. With increased allelic recovery in addition to decreased stochastic events as compared to other LCN methods, an improved protocol for LCN samples will increase the ability of forensic laboratories to generate useful profiles.

Producing genetic profiles from samples with 100pg or less of template DNA, also known as LCN samples, is difficult using standard PCR methods. Modified sample preparation protocols which increase the cycle number used for amplification up to 34 cycles have been developed to improve profile recovery from these sample types; however, increasing the PCR cycle number produces allelic imbalance and drop out as well as other stochastically induced events, such as increased stutter ratios. Increasing the number of PCR cycles can result in either more complex mixtures due to the amplification of trace DNA that would not otherwise be detected or in the amplification of trace DNA contaminants introduced during sample processing that would not otherwise have been detected. These effects can complicate the interpretation of resulting STR profiles. The method assessed in this study seeks to increase the percent recovery of a genetic profile as compared to standard PCR methods without producing the increased stochastic effects observed with increased cycle number methods.

Dilutions of extracted reference quality DNA were prepared so that the maximum input volume for amplification (in this case 17.5µl) would result in the addition of the following amounts of DNA: 245pg, 122.5pg, 85.8pg, 42.9pg, 30.0pg, 15.0pg, 10.5pg, 5.3pg, 3.7pg, and 1.8pg. Autosomal STR profiles were developed from each dilution in the series by four different assay methods (five replicates each). Samples in treatment group one were amplified following the manufacturer's recommended protocol with 30 amplification cycles. Samples in treatment group two were amplified following the manufacturer's recommended protocol with the addition of four extra amplification cycles (34 amplification cycles total). Samples in treatment group three followed the manufacturer's recommended protocol with 30 amplification cycles except that 50µl of DNA extract was dried down and reconstituted in 17.5µl TE⁻⁴, thus resulting in a greater overall input of DNA. Samples in treatment group four followed the manufacturer's recommended protocol with 30 amplification cycles except that 50µl of DNA extract was added to a centrifugal filter and concentrated in 17.5µl TE⁻⁴, thus resulting in a greater overall input of DNA. All samples were amplified using an Applied Biosystems® GeneAmp® PCR System 9700 using a Promega® PowerPlex® 16 HS System and analyzed using capillary electrophoresis on an Applied Biosystems® 3130 Genetic Analyzer. Resulting genetic profiles were compared based on percent recovery of donor alleles, stutter ratios, and allelic balance, as well as for allelic drop in.

Full DNA profiles were consistently obtained with as little as 15pg template DNA for dried down samples. Samples at the same initial concentration, 0.30pg/µl, only yielded 35.5%, 45.8%, and 29% of donor alleles for standard samples, increased cycle number samples, and samples concentrated with filters prior to amplification, respectively. When compared to samples with the same input of template DNA prepared following the other methods, dried down samples did not show significant increased stutter nor was any peak height imbalance or allelic drop-in observed; however, increased stutter, peak height imbalance, and drop-in was observed in those samples that underwent increased PCR cycle number. Several replicates of dried down samples even produced full profiles with only 10pg template DNA. Resulting data illustrates that concentrating extracts prior to amplification by drying them down is a method well suited for use in forensic biology laboratories when attempting to develop genetic profiles from low copy number samples.

STR Typing, LCN DNA, PowerPlex® 16HS

B139 Use of the Ion PGM™ System for Typing Human Identity Marker Systems

*Jennifer D. Churchill, PhD**, 429 College Avenue, Apt 209, Fort Worth, TX 76104; *Joseph P. Chang, BS*, Thermo Fisher Scientific, 180 Oyster Point Boulevard, South San Francisco, CA 94080; *Jianye Ge, PhD*, Thermo Fisher Scientific, 180 Oyster Point Boulevard, South San Francisco, CA 94080; *Narasimhan Rajagopalan, MS*, Thermo Fisher Scientific, 180 Oyster Point Boulevard, South San Francisco, CA 94080; *Robert Lagacé, BS*, Thermo Fisher Scientific, 180 Oyster Point Boulevard, South San Francisco, CA 94080; *Wenchi Liao*, 180 Oyster Point Boulevard, South San Francisco, CA 94080; *Jonathan King, MS*, 3500 Camp Bowie Boulevard, Fort Worth, TX 76107; and *Bruce Budowle, PhD*, UNT Health Science Center, Forensic & Investigative Gen, 3500 Camp Bowie Boulevard, EAD 310, Fort Worth, TX 76107

After attending this presentation, attendees will understand the methodology and sequencing chemistry used in massively parallel sequencing on the Ion Personal Genome Machine® (PGM™) platform and the capability of this system to sequence and interpret large genetic marker panels.

This presentation will impact the forensic science community by providing current progress on the use of massively parallel sequencing as it pertains to forensic DNA analysis. In addition, attendees will learn about the quantity and quality of the data generated by Ion PGM™ system.

Massively Parallel Sequencing (MPS), also known as next generation sequencing, technologies provide the scientific community with novel and enhanced approaches to DNA typing. While capillary electrophoresis-based technologies have been considered the gold standard for human identity typing applications, the current technology has notable limitations in intra-repeat variation resolution, sample scalability, and throughput of markers that can be typed. MPS has the potential to overcome these limitations with its ability to multiplex different types of forensically relevant genetic markers, analyze a large number of markers simultaneously, and sequence multiple samples per run. Additionally, MPS data may offer a new avenue for interpretation of mixtures. The Ion Torrent™ PGM™ is a benchtop sequencer that uses semiconductor sequencing chemistries and laboratory workflows that enable high-throughput and quick run times at a reasonable cost.

Twelve genomic samples, containing total DNA ranging from ~42ng to 280ng, were provided by a third party (the Green Mountain Conference) for a blinded genetic study. The mitochondrial genome and three Ion PGM™ panels containing human identity Single Nucleotide Polymorphisms (SNPs), ancestry informative SNPs, and Short Tandem Repeats (STRs) were sequenced on the Ion PGM™ system and analyzed for these 12 samples. Sequencing and genetic analysis for all four genetic systems were completed in a reasonably quick time frame by one individual. Completeness of genetic profiles, depth of coverage, strand balance, and allele balance were evaluated as informative metrics for the quality and reliability of the data produced. The autosomal SNPs from the human identity SNP panel reached an average read depth of 2,233. For this study, 99% of these SNPs had an average strand balance of 60% to 100%, and 100% of these SNPs had an average allele coverage ratio of 30% to 50%. The Y-chromosome Single Nucleotide Polymorphisms (Y-SNPs) from the human identity panel reached an average read depth of 975 while 97% of these SNPs had an average strand balance of 60 to 100 percent. The SNPs from the ancestry SNP panel reached an average read depth of 1,511 and 98% of these SNPs had an average strand balance ratio of 60% to 100% and 94% of these SNPs had an average allele coverage ratio of 30% to 50%. The large number of SNPs in these panels provides information on individual identification, familial relationships, and population background for the samples analyzed. The average allele coverage ratios for the STR markers ranged from 70% to 100% and the STR genotypes generated by MPS were in complete concordance with genotypes generated by standard capillary electrophoresis-based technologies. Additionally, intra-STR SNPs identified by MPS offer the potential for increased discriminatory power and improvement in mixture analysis. MPS coverage across the entire mitochondrial genome ranged from 489 to 7,029 in read depth. The average percent positive strand coverage for the entire mitochondrial genome ranged from 30% to 86% and indicated that sequence data from both strands of the mitochondrial DNA were captured. Mitochondrial variants identified among this sequence data were used to generate haplogroups for each sample and ultimately provide information on population background and maternal relationships. Sample information provided by Green Mountain subsequent to the blinded study supported that reliable results had been produced for all 12 genomic samples. The strength and depth of these results warrant expanded validation studies of current MPS technologies (which are ongoing) and continued development of tools for data analysis.

Massively Parallel Sequencing, Forensic DNA Typing, Human Identity

B140 Increased Ancestry Prediction of the United States Population Using Short Tandem Repeat (STR) Data in Addition to 32 Ancestry-Informative SNPs

Valerie Clermont Beaudoin, BS, 1930 37th Street, NW, Washington, DC 20007; Katherine B. Gettings, PhD, NIST, 100 Bureau Drive, Mail Stop 8314, Gaithersburg, MD 20899; Moses S. Schanfield, PhD, Dept of Forensic Sciences-GWU, 2100 Foxhall Road, Washington, DC 20007; and Daniele S. Podini, PhD, Department of Forensic Science, 2100 Foxhall Road, NW, Washington, DC 20007*

After attending this presentation, attendees will learn that the STRs used for Human Identification (HID) can support Single Nucleotide Polymorphisms (SNPs)-based ancestry prediction on United States-population individuals.

This presentation will impact the forensic science community by demonstrating that STRs can aid in increasing the accuracy of ancestry inference.

Often a very limited amount of information is available on the perpetrator of a crime, especially when there are no eyewitnesses, when the DNA left behind does not match any suspect, or the DNA isn't present in the databases; however, it is still possible to garner investigational information by analyzing Ancestry-Informative SNPs (AISNPs). An SNP assay was developed at George Washington University that predicts the most likely ancestry of an individual between the primary United States populations (grouped as African American, East Asian, European American, and Hispanic/Native American). The prediction is made by first determining the probability of the SNP profile within each population (i.e., the Random Match Probability (RMP)). The RMP is the probability of randomly finding an unknown individual with that specific profile in the given population. Then a Likelihood Ratio (LR) is calculated for each of the four populations. In this LR, the numerator is the RMP of the SNP profile from the population in which it is highest and the denominator is the RMP of the profile in the specified population. The LR expresses how much more likely it is to observe the profile if it originated from the population in the numerator versus if it originated from the population in the denominator. An empirical threshold of 1,000 was chosen, above which it is considered significant for a sample to be classified as belonging to one of the four populations. A sample with an LR lower than 1,000 was classified as inconclusive between the two populations with the highest RMPs, inferring that the sample most likely belongs to one or both of those populations. The samples are divided into four categories based on the results obtained: correct, incorrect, inconclusive correct, and inconclusive incorrect. Correct corresponds to the situation where the sample is classified as belonging to a single population, which is the same one as reported by the donor. Incorrect corresponds to the situation where the sample is classified as belonging to the wrong population. Inconclusive correct corresponds to the situation where the sample is classified as belonging to two populations and the donor reported one or both of these populations. Inconclusive incorrect corresponds to the situation where the sample is classified as belonging to two populations but these populations were not reported by the donor.

Thirty-two AISNPs were used to predict the ancestry of 134 samples (with self-reported ancestry information) using the method described above. Of these samples, 72% were correctly classified as belonging to one population. One sample was classified as inconclusive incorrect. The rest of the samples (27%) were classified as inconclusive correct. No samples were classified as incorrect.

To assess the impact of including HID STR allele frequencies into the ancestry prediction, the 134 samples were also genotyped with AmpflSTR® Identifier® Plus. The random match probability was calculated with the STR data obtained and factored into the SNP RMPs. The LRs were then recalculated and the accuracy of the prediction was reevaluated. With the inclusion of the STR data in the analysis, the accuracy of the prediction increased to 80% correctly classified samples. This 8% increase is statistically significant at a 95% confidence (Z -score=-1.7252154; p =0.0422). This indicates that although STRs were not selected to provide ancestry information, they can improve the prediction of an SNP-based assay. Thus, available STR data should be included in ancestry prediction.

SNPs, Ancestry Prediction, STRs

B141 Simulating the United Arab Emirates Crime Scene Samples and Generating DNA Profiles From Them Using the RapidHIT™ System

Aamer Alshehhi, BS, Penn State University, Forensic Science Program, 107 Whitmore Laboratory, University Park, State College, PA 16802; and Reena Roy, PhD, Pennsylvania State University, Forensic Science Program, 325 Whitmore Lab, University Park, PA 16802*

After attending this presentation, attendees will understand how quickly DNA profiles can be obtained from environmentally challenged samples even by non-scientists.

This presentation will impact the forensic science community by demonstrating that a robust automated system can be used to obtain DNA profiles from samples exposed to detrimental environmental conditions.

The average time needed to obtain a DNA profile from an evidence sample in crime laboratories is approximately 12 hours, which is time-consuming and labor intensive. In contrast, the RapidHIT™ Human DNA Identification System provides a faster method to generate DNA profiles in approximately 90 minutes. The operator only needs to insert the samples in the instrument cartridge. The system then extracts, amplifies, and generates DNA profiles through capillary electrophoresis.

The goal of this research was to test the sensitivity and robustness of the newly introduced “Run Other Samples” instrument protocol of the RapidHIT™ System in generating DNA profiles from simulated crime scene samples. The samples used in this study were blood and saliva, with varying amounts of each deposited on different types of substrates. The blood samples were obtained from one deceased male and one deceased female. The saliva sample was obtained from a living female donor.

The substrates chosen for this study are commonly found in crime scenes in the United Arab Emirates. The substrates used for deposition of saliva samples included cotton swabs, cotton-tipped applicators, stainless steel spoons, plastic spoons and forks, straw, mint-flavored chewing gum, stones covered with soil, the mouth area of water bottles, stamps, envelopes, and oil-based paint. Blood was deposited on substrates that included cotton swabs, cotton-tipped applicators, paper coated with latex-based paint, paper coated with water-color paint, tile, finished wood flooring, unfinished wood blocks, laminated flooring, broken tempered glass, stones covered with soil, pieces of wood covered with soil, denim jeans, synthetic leather, carpet fibers, delicate task wipes, clear plastic bags, and white scarves typically worn by men in the United Arab Emirates. Similar amounts of blood from deceased donors and an approximately similar amount of saliva from a living donor were deposited on each of these items. The substrates containing body fluids were then kept at room temperature for approximately 24 hours. Furthermore, the substrates were environmentally challenged by heat and humidity, factors similar to the weather conditions encountered in the United Arab Emirates.

Each substrate containing one body fluid was either swabbed or cut and deposited in cartridges using the RapidHIT™ System. Autosomal Short Tandem Repeat (STR) loci and the amelogenin gender locus were amplified using the PowerPlex®16 HS multiplex amplification kit chemistry. The generated data were analyzed using GeneMarker® HID Software Version 2.4.0. The DNA profiles were compared for concordance within and between the substrates used in this study.

This study shows that the RapidHIT™ System is capable of producing complete and concordant profiles from blood and saliva samples deposited on simulated crime scene substrates commonly encountered in the United Arab Emirates. The “Run Other Samples” instrument protocol worked effectively to generate DNA profiles from pristine and challenged samples.

Complete profiles were obtained from all of the 87 samples tested. Replicates were not run since full profiles were generated from all 87 samples. The Peak Height Ratios (PHR) and the Relative Fluorescence Units (RFU) values decreased with decreased volumes of blood. The PHR values were above 70% with 1.0µl, 0.5µl, and 0.25µl of blood while PHR values below 70% were observed when 0.125µl and 0.0625µl of blood were amplified.

DNA profiles with all 16 loci were obtained from 1.0µl, 0.5µl, 0.25µl, and 0.125µl of the neat male blood sample. Additionally, 50.0µl, 40.0µl, 30.0µl, 20.0µl, and 10.0µl of saliva directly deposited on the swabs yielded complete DNA profiles. As expected, PHR values decreased when the amount of saliva was reduced.

Various volumes of the blood and saliva samples deposited on different, potentially inhibiting substrates generated complete profiles with excellent peak signals and balanced peak height ratios. Additionally, high heat and humidity similar to that experienced in the United Arab Emirates did not adversely affect the RapidHIT™ System’s ability to yield complete profiles on simulated crime scene samples.

B142 Development of a Portable, Laminated Dynamic Solid-Phase DNA Extraction Method on a Rotationally-Driven Platform

Kimberly Jackson*, 409 McCormick Road, Chemistry Dept, Charlottesville, VA 22903; Juliane Cristina Borba, MS, Instituto de Química de São Carlos - USP, Avenida Trabalhador São Carlense, 400, Sao Carlos, São Paulo 780, BRAZIL; Brian L. Poe, PhD, University of Virginia, 409 McCormick Road, Chemistry Dept, Charlottesville, VA 22903; Emanuel Carrilho, PhD, Universidade de São Paulo, Instituto de Química de São Carlos, Av. Trabalhador Sao-carlense, 400, Sao Carlos, SP 13566-590, BRAZIL; Roman Aranda, IV, PhD, Defense Forensic Science Center, Office of the Chief Scientist, 4930 N 31st Street, Forest Park, GA 30297; Karen Olson, PhD, Defense Forensic Science Center, 4930 N 31st Street, Forest Park, GA 30297; Doris Haverstick, PhD, University of Virginia, 409 McCormick Road, Charlottesville, VA 22903; and James P. Landers, PhD, University of Virginia, Dept of Chemistry, McCormick Road, Charlottesville, VA 22904

After attending this presentation, attendees will better understand the growing field of microfluidics and the design and development toward a novel, inexpensive, and portable alternative for extracting DNA from forensically relevant samples.

This presentation will impact the forensic science community by introducing a technique that adapts DNA extraction to a microfluidic platform for the potential of an inexpensive, on-site DNA extraction system in resource-limited areas with increased sample efficiency compared to current benchtop methods.

Solid-Phase Extraction (SPE), a critical step in genetic analysis, relies on the binding of DNA to silica-coated particles.¹ Dynamic SPE (dSPE) manipulates silica-coated magnetic particles during the extraction process to ensure optimized trapping and elution of DNA. Adapting dSPE to a microdevice enables advantages over benchtop methods including: increased sample efficiency, decreased reagent volumes, decreased assay cost, a closed system to prevent contamination, and the ability for integration with downstream processing via STR or next generation sequencing.

Polyester (Pe) can be patterned and bonded with Toner (T) to create multilayer microfluidic PeT devices for <\$2 in <15 minutes.^{2,3} Successful demonstration of dSPE via pressure-driven flow in rapidly fabricated PeT devices has been shown via manual pipetting.² Recent developments with open architecture PeT devices, hydrophobic valving, and centrifugally-driven fluid flow provide an attractive new platform for automated dSPE. The proposed dSPE system functions at low spin speeds (<1,500rpm), incorporates valving for non-aqueous solutions, is low cost (\$0.25 per assay), and is amenable to rapid, simple fabrication. For the first time, DNA extraction from whole blood on a disposable plastic PeT microdevice using an automated, rotationally-driven platform is described.

The proposed PeT microdevice is composed of four layers and is fabricated using laser printer lithography. The device, when loaded with dSPE reagents and sample, can be run through a five-speed bidirectional spin program (0 to ~1,276rpm) on the home-built system. Binding of sample DNA to the particles is driven by an Alternating Magnetic Field (AMF). A novel combination of a hydrophobic valve and backpressure prevents the wash and elution buffers from entering the bound DNA chamber. After binding, IPA is released by centrifugal force (overcoming backpressure) at ~293rpm, followed by a TE wash through hydrophobic valve bursts at ~340rpm. After washing, the bound DNA is eluted and mobilized to a separate elution chamber at ~1,276rpm using “stop” valves positioned below the main DNA chamber. Approximately 10 μ l of purified DNA results from this process and is accessible by puncturing the Poly(DiMethyl) Siloxane (PDMS) covering the elution chamber. To demonstrate that the spin system effectively purifies PCR-ready DNA from 2 μ L of whole blood, the target β -globin was successfully amplified via microchip electrophoresis. In addition, samples extracted from FTA[®] cards were successfully amplified for STR analysis and were shown to display full profiles.

The proposed PeT microdevice has the potential to extract forensically-relevant samples when compared to the Qiagen[®] EZ1[®] instrument. Preliminary results suggest that DNA extracted from the microdevice and the EZ1[®] from buccal swabs were nearly equivalent in concentration, 0.28 \pm 0.1ng/ μ L and 0.27 \pm 0.7ng/ μ L, respectively. Furthermore, full STR profiles have been obtained with both methods. PeT-based peak heights were 1,619 \pm 1,054 Relative Fluorescence Units (RFUs) compared to the EZ1[®] peak heights at 1,774 \pm 705 RFU. Current efforts are underway to increase extraction efficiency and reproducibility. Overall, this is the first demonstration of a PeT microdevice used for chaotrope-driven dSPE on a rotationally-driven platform. The portable system has the potential to provide a cost-effective alternative to current SPE kits and once fully optimized, can be coupled to other pre- and post-processing DNA steps including preliminary DNA detection and amplification.

B143 Use of Rapid DNA Systems in Disaster Victim Identification

Sheila E. Dennis, MS, OCME, New York City Office, Dept of Forensic Biology, 421 E 26th Street, New York, NY 10016; Yvette Rada, MS, NYC OCME, Dept of Forensic Biology, 421 E 26th St, New York, NY 10016; Desarae L. Harmon, BS, NYC OCME, Dept of Forensic Biology, 421 E 26th Street, New York, NY 10016; Zoran M. Budimlija, MD, PhD, 201 E 69th Street, #9M, New York, NY 10021; and Grace L. Axler-DiPerte, PhD, 421 E 26th Street, New York, NY 10306*

After attending this presentation, attendees will understand how Rapid DNA systems can be implemented for use in disaster victim identification.

This presentation will impact the forensic science community by informing attendees about how Rapid DNA systems can shorten the time it takes to process, compare, and identify victims of a mass fatality incident.

Disaster Victim Identification (DVI) can be a very meticulous and lengthy process despite the number of casualties. This is especially true if DNA testing is part of the DVI process and is used to assist in the identification of victims. Processing and analyzing DNA samples from decedents or relatives can take several days. Rapid DNA typing systems eliminate this wait by utilizing a tabletop, self-contained, and automated instrument. Within the past few years, several companies have developed and improved such systems. Rapid DNA systems reduce the time needed to process a DNA sample from days to less than two hours. In contrast, traditional methods of DNA profiling from cheek swabs require upwards of ten hours and involve multiple laboratory personnel. The currently available rapid DNA systems allow for DNA extraction, amplification, separation, and genotyping analysis to be completed in less than 90 minutes, without analyst intervention. This represents a significant savings of time and personnel over traditional STR typing methods. Among the rapid DNA instruments that are available, each generates a DNA profile in a similar manner but with varying sample capacity, run times, and cost.

Rapid DNA systems are particularly practical for disaster recovery and identification. Besides being fast, the systems are mobile, rugged, and simple to use, with all consumables provided in a disposable, ready-for-use format. With rapid DNA systems on-site at a Family Assistance Center (FAC), DNA analysis of samples collected from family members can be processed and the resulting DNA profiles analyzed in a family pedigree chart.

Concurrently, if disaster recovery is occurring and a mobile morgue is set up, postmortem samples can be collected on-site and processed immediately. Transport, sample tracking at the laboratory, and the requirements of multiple laboratory personnel are eliminated. The DNA team at the mobile morgue can collect and process samples immediately. The profiles generated from decedents at the mobile morgue and relatives at the FAC can be readily input into a current victim identification program and kinship analysis performed.

The New York City Office of Chief Medical Examiner (NYC OCME) Department of Forensic Biology has evaluated two rapid DNA systems in order to evaluate their application for DVI: the IntegenX RapidHIT® Human Identification System and GE Healthcare Life Sciences (GE) and NetBio DNAScan™ Rapid DNA Analysis™ System. Initial evaluations were conducted at the NYC OCME and the performance of each instrument was further evaluated at a full-scale mass disaster exercise. Specifically, the RapidHIT® and DNAScan™ Rapid DNA systems were evaluated on-site at the FAC and DNA unit of the mobile morgue during the Fifth Annual Regional Mass Fatality Management (MFM) Training, which occurred from June 2 to 6, 2014, at Fort Hamilton Army Base in Brooklyn, NY. During the FAC portion of the exercise, reference samples were collected from volunteers simulating family members and processed on both instruments. During the mobile morgue portion of the exercise, eight postmortem muscle and two postmortem blood samples, simulating recovered remains, were processed and typed in the DNA unit of the mobile morgue on both instruments. Samples were loaded into either the RapidHIT® system sample cartridges or the DNAScan™ BioChipSet™ cassette, both using Promega's® PowerPlex® 16 HS kit optimized for rapid DNA analysis. The DNAScan™ data were automatically analyzed using NetBio's integrated software with fixed analysis parameters. The RapidHIT® data were automatically analyzed with the on-board SoftGenetics® GeneMarker® HID STR Human Identity Software.

The output data for both rapid DNA systems were compared to a reference database of traditionally-typed STR profiles. Output data were also manually confirmed by a DNA analyst and evaluated based on alleles called, profile completeness, and peak height balance. See data in Tables 1 and 2 below.

The MFM exercise has demonstrated that rapid DNA systems can be utilized in DVI. Sample preparation for input into cassettes, respective software analysis parameters, and logistics, as far as instrument transport and chip storage, need to be considered and incorporated into a standard operating procedure for rapid DNA system operations in DVI.

B144 Human Identification in Less Than 45 Minutes: A Rapid and Fully Portable DNA Solution

Nani M. Grimmer, BS, The Bode Technology Group, Inc, 10430 Furnace Road, Ste 107, Lorton, VA 22079; Michael N. Parsons, MS, 10430 Furnace Road, Ste 107, Lorton, VA 22079; Abigail S. Bathrick, MFS, 10430 Furnace Drive, Lorton, VA 22079; Katie Kennedy, BS, The Bode Technology Group, Inc, 10430 Furnace Road, Ste 107, Lorton, VA 22079; and Donia Slack, 10430 Furnace Road, Ste 107, Lorton, VA 22079*

After attending this presentation, attendees will be aware of an ongoing effort to develop a human DNA identification system that provides a discriminatory power of more than 98% and is performed on a commercially available, rapid, portable, and ruggedized instrument. Attendees will gain insight into the research and development of the system and the flexibility of using Single Nucleotide Polymorphisms (SNPs) for DNA identification.

This presentation will impact the forensic science community by introducing a system that can be used to develop investigative leads through the analysis of biological evidence on-site at crime scenes or areas of interests. The presented system will also support the applicability of SNPs to forensic DNA technologies and human identification.

In recent years, major progress has been made toward the development of fully integrated rapid DNA analysis devices; however, most of these instruments are not amenable to on-site DNA processing at the crime scene due to their size. Overall, the existing rapid DNA devices are large and mobile laboratories would be necessary to transport the systems to a crime scene. To address the need for a portable rapid DNA analysis system, The Bode Technology™ Group, Inc. has developed a human identification SNP assay for use with the RAZOR® EX instrument. The RAZOR® EX is a lightweight real-time thermal cycler typically used for the detection and identification of pathogens and biothreat agents. Commercially available RAZOR® EX assays are performed in under an hour using a rapid extraction method and a specialized pouch containing lyophilized amplification reagents. Additionally, the device has an on-board Liquid Crystal Display (LCD) screen that displays the assay results in real time.

To adapt the RAZOR® EX instrument for human DNA analysis, a multiphased approach was taken for development of a human identification system: (1) a simple, rapid, and efficient extraction method was created that is capable of lysing blood, semen, and epithelial cells in less than 15 seconds; (2) a customized TaqMan® allelic discrimination assay capable of amplifying forensic samples was developed using SNPs that were previously characterized for forensic use; (3) two amplification controls were designed to estimate the quantity and quality of the forensic sample; and, (4) the amplification reagents were lyophilized to ensure the stability of the assay at room temperature. While the assay results can be easily interpreted from the RAZOR® EX's LCD screen, a software application was also developed to provide more accurate data analysis and to allow population statistics to be applied to the sample. The entire process, from collection to result, has been performed on mock evidentiary samples in less than 45 minutes.

The current version of the rapid portable human identification system has generated robust results both in the laboratory and in mock field testing. The discriminatory SNP assays have been tested on over 400 forensically relevant samples. Prior to lyophilization, initial wet assay testing examined 25µL of blood (neat and diluted 1:50), semen (neat and diluted 1:50), and saliva (neat and diluted 1:10) deposited on glass, plastic, rusted metal, adobe brick, red brick, concrete, ceiling tile, MDF, duct tape, plywood, cotton fabric, denim, and paper. Full SNP profiles were generated from 100%, 86.5%, and 43.6% of the neat blood, semen, and saliva samples, respectively. As expected, fewer full profiles were generated from the diluted fluid samples, with a 30.8% success rate for diluted blood, a 23.1% success rate for diluted semen, and a 28.2% success rate for diluted saliva. Across all sample types, assay success rates were higher for samples deposited on non-porous substrates. Following lyophilization of the assay, 27 mock forensic samples were amplified with the lyophilized pouches on-site at mock crime scenes. The mock forensic samples consisted of blood, semen, and saliva (100µL) deposited onto metal, concrete, plastic, and cotton substrates that were exposed to uncontrolled indoor or outdoor conditions for a minimum of 12 months. Of these samples, 67% generated full SNP profiles. Additional controlled laboratory testing has been performed to examine the reproducibility and sensitivity of the lyophilized assay. A full developmental validation is anticipated to determine the system limitations.

B145 Validated and Straightforward Multiplex PCR Method for High-Quality Analysis of the Expanded CODIS STR Loci Set

Daniel Müller, Qiagen Str. 1, Hilden, NRW, GERMANY; Melanie Breitbach, QIAGEN GmbH, QIAGEN Street 1, Hilden 40724, GERMANY; Stefan Cornelius, QIAGEN, QIAGEN Street 1, Hilden 40724, GERMANY; Sarah Pakulla-Dickel, QIAGEN, QIAGEN Street 1, Hilden 40724, GERMANY; Margaretha Koenig, QIAGEN, QIAGEN Street 1, Hilden 40724, GERMANY; Anke Prochnow, MD, QIAGEN GmbH, QIAGEN Street 1, Hilden 40724, GERMANY; Lars Bochmann, MD, QIAGEN, QIAGEN Street 1, Hilden 40724, GERMANY; Mario Scherer, PhD, Qiagen-Strasse 1, Hilden 40724, GERMANY; and Ralf Peist, MD, QIAGEN, QIAGEN Street 1, Hilden 40724, GERMANY*

After attending this presentation, attendees will know about the benefits of QIAGEN's® Combined DNA Index System (CODIS) expansion Polymerase Chain Reaction (PCR) kit, how to evaluate the amplification efficiency of the PCR in a very convenient way, and how to choose the most appropriate rework strategy.

This presentation will impact the forensic science community by showing new technical features for a Short Tandem Repeat (STR) analysis with the benefits of reducing costs and increasing efficiency, productivity, and quality for laboratory operations by using the unique and novel quality sensor system.

QIAGEN® has developed and validated two multiplex PCR kits for reliable genotyping of the expanded CODIS STR loci set: the Investigator® 24plex QS Kit and the Investigator® GO! Kit. The former kit is designed for purified DNA from casework and reference samples, the latter kit is optimized for direct amplification of reference samples, like blood or buccal cells on FTA® paper or swabs. For buccal swabs, a five-minute lysis protocol is provided to prepare samples for direct amplification.

To verify the quality of the DNA sample and the performance of the PCR, both kits contain a novel quality sensor as an internal performance control. Forensic analysts are often faced with challenges when it comes to interpreting STR results. What is the reason that no peaks are visible in the electropherogram? Did the PCR fail? Was the DNA concentration too low? Was the DNA degraded? The kits of the Investigator® 24plex family contain a unique and novel Quality Sensor that is useful for evaluating the amplification of the PCR reaction. The system consists of two internal PCR controls (Quality Sensor QS1 and Quality Sensor QS2) located at the borders of the purple dye channel at 74bp and 435bp, respectively. To ensure that the quality controls do not cause any unspecific amplification during PCR, the internal control template was designed using a random algorithm and the obtained sequences were checked for absence of significant similarity to any known sequences. The 74bp QS1 shows very stable amplification, even in the presence of extremely high inhibitor concentrations (e.g., 1,000µM hematin). In contrast, the 435bp QS2 is more prone to inhibition and typically drops out before the first STR marker drop out is observed. Relative signal heights of QS1 and QS2 can thus be used to indicate inhibition. In the case where both sensors are unaffected but the sample shows a ski-slope effect with poor amplification of high molecular weight markers, degradation of the DNA sample is most likely. This information can be used to choose the most appropriate rework strategy.

Both assays use a new 6-dye technology to shorten the overall amplicon length and minimize overlap of the 23 markers which might lead to errors in data interpretation. The kits feature a very robust gender typing by offering small amplification fragments both for amelogenin and DYS319, leading to correct gender typing even for difficult samples (degraded or inhibited DNA) of amelogenin null mutant individuals. The developmental validation of the Investigator® 24plex QS kit based on the revised guidelines of the Scientific Working Group on DNA Analysis Methods (SWGDM) and the recommendations of the European Network of Forensic Science Institutes (ENFSI) has recently been completed. In a sensitivity study, full profiles were consistently obtained with 125pg template DNA. First stochastic allele drop outs were observed at 63pg template. Inhibitor studies revealed full DNA profiles in the presence of up to 200ng/µl humic acid, 750µM hematin, 3mM calcium, 12mM indigo carmine, 4000ng/µl tannic acid, and 200ng/µl collagen. These kits are in the process of being evaluated for approval for use at the National DNA Index System (NDIS).

CODIS, PCR, Quality

B146 Improving Processing Efficiency for Forensic DNA Samples

Catherine Cupples Cannon*, Cellmark Forensics, 13988 Diplomat Drive, Ste 100, Farmers Branch, TX 75234; Aaron K. LeFebvre, PhD, Orchid Cellmark, Inc, 13988 Diplomat Drive, Ste 100, Dallas, TX 75234; and Robert C. Benjamin, PhD, University of North Texas, 1155 Union Circle, #305220, Denton, TX 76203

After attending this presentation, attendees will be familiar with several approaches used to reduce sample processing time by ~33% for databasing reference samples, including extraction normalization, fast Polymerase Chain Reaction (PCR), and quicker genetic analyzer detection while maintaining high-quality profiles similar to those observed using current methods (i.e., >90% full profiles using 3100 rfu threshold with 100% concordant alleles, comparable inter-locus peak balance, PHR $^350\%$, stutter $\leq 20\%$, pull-up $\leq 20\%$, and no -A).

This presentation will impact the forensic science community by sharing methodologies to significantly improve sample-processing efficiency without the need to purchase new instrumentation or costly reagents. These improvements are robust and can be implemented in a variety of laboratory settings.

The goal of this project was to reduce processing time without incurring significant added costs via a multi-layered overhaul undertaken in the following order: (1) develop a quicker detection method for the 3130xl Genetic Analyzer using an alternative polymer/array length combination; (2) develop fast PCR protocols for various Short Tandem Repeat (STR) primer sets using shorter amplification parameters, low volume reactions, and standard non-fast thermal cyclers; and, (3) normalize an extraction process using the ChargeSwitch® Forensic DNA Purification Kit such that a small range of yields are consistently obtained, thereby eliminating the need for quantification and dilution prior to amplification.

First, alternative polymer and capillary array length combinations were evaluated and compared to the standard POP-4™/36cm array detection method employed for STR detection on a 3130xl Genetic Analyzer. Detection time for standard 4-dye and 5-dye STR amplification kits was reduced to ~25 minutes using POP-6™/22cm array by modifying numerous injection parameters. STR profile quality was evaluated via concordance, dropout, peak height, resolution, ILS sizing quality/migration, pull-up, -A, and background noise. Validation for 4-dye and 5-dye amplification kits consisted of ~200 samples per dye set and studies included precision, resolution, injection time, and comparison to POP-4™/36cm array detection. POP-6™/22cm array detection achieved 0.5bp precision for up to 250bp fragments and 1bp resolution, which are the advertised specifications for POP-4™/36cm array detection.

Next, four fast PCR reagents were evaluated using the Identifiler® primer set, including AmpliTaq® Gold Fast PCR Master Mix, KAPA2G™ Fast Multiplex PCR Kit, SpeedSTAR™ HS DNA Polymerase, and Type-it® Microsatellite PCR Kit. Profiles were evaluated via concordance, dropout, peak height, inter- and intra-locus peak balance, stutter, pull-up, -A, specificity, and background noise. In addition to profile quality, amplification time, reagent cost, and ease of PCR setup were also taken into account. Using these criteria, KAPA2G™ Fast Multiplex PCR Kit was selected to develop and validate fast protocols for the Identifiler®, Identifiler® Plus, and PowerPlex® 16 HS primer sets, using reaction volumes ranging from 3µl to 6µl and two non-fast thermal cyclers (384-well Veriti® and 96-well GeneAmp® PCR System 9700) with amplification times ranging from 43 to 51 minutes. Fast PCR validations consisted of ~200 samples and studies included sensitivity, reproducibility, precision, stochastic, comparison to standard PCR, and contamination. Sensitivity ranged from 0.1875ng to 3.0ng, but optimal DNA input ranged from 0.375ng to 1.5ng for each primer set and amplification volume.

Lastly, extraction normalization for the ChargeSwitch® Forensic DNA Purification Kit included a reduction in the quantity of magnetic beads used per sample and targeted final concentrations of ~0.42ng/µl to 1.63ng/µl for 3µl amplifications and ~0.21ng/µl to 0.83ng/µl for 6µl amplifications. As a result, the need for quantification and dilution of each sample prior to amplification was eliminated. It should be noted that this approach is only acceptable for reference samples (see Standard 9.4 of the 2011 Federal Bureau of Investigation (FBI) Quality Assurance Standards). Validation of the new process (normalized extraction plus fast PCR amplification and POP-6™ detection) included >200 samples and studies included reproducibility, precision, comparison to the current process, and contamination. Profiles were evaluated as described above and were as good as those obtained using the current process.

Criminalistics Section - 2015

Implementation of this or a similar approach reduces start-to-finish processing time to approximately a single workday. Furthermore, results from these studies indicate that a significant reduction in sample processing time is possible without the need to purchase costly instrumentation or reagents and will enable a laboratory to decrease their number of instruments needed to maintain their sample throughput or, alternatively, to increase sample throughput by maintaining the same number of instruments.

Forensic DNA, Fast PCR, Quicker 3130xl Detection

B147 Microtrace to Nanotrace: Extracting Information at Increasingly Smaller Length Scales

*Christopher S. Palenik, PhD**, Microtrace, 790 Fletcher Drive, Ste 106, Elgin, IL 60123-4755; and *Skip Palenik, BS**, Microtrace, 790 Fletcher Drive, Ste 106, Elgin, IL 60123-4755

After attending this presentation, attendees will understand that presently the majority of trace evidence examinations focus on features and particles larger than 10 micrometers in size. Highly engineered and naturally occurring particles in the low micrometer- to nanometer-size range surround us and are seeing more use each year.

This presentation will impact the forensic science community by providing a primer to the forensic science community on the potential value, analytical approaches, and concerns that must be addressed when approaching particles at this length scale.

In the spirit of this year's conference theme, "Celebrating the Forensic Science Family," this double-feature, father-son presentation will discuss the benefits, significance, and, ultimately, the need to find and extract information from increasingly smaller amounts of trace evidence. Presented from two perspectives, one couched in the rich history of forensic science and its founders, the other taken from the exciting potential in new and higher-resolution methods, both authors arrive at common ground in recognizing the importance of visual evidence as seen through the microscope.

For more than a century, scientists have exploited the value of small particles through trace evidence. While hardly a novel concept in itself, three factors have caused us to explore and consider its significance in terms of increasingly smaller features and particles in the context of trace evidence. The first is a consequence of the *CSI*-effect. Savvy criminals are often aware of trace evidence and, in some instances, make active efforts to minimize these contacts. Secondly, as society enters the age of nanotechnology, highly engineered particles, layers, and features of materials are becoming increasingly smaller while, at the same time, becoming more complex. As paint layers reach the sub-10 micrometer range, multilayer film layers reach the nanometer scale, and free nanoparticles begin to find regular commercial use in a wide range of consumer products such as cosmetics, glass, fibers, and paint. Finally, robust and practical microanalytical methods of light and electron microscopy combined with vibrational micro-spectroscopy provide the means by which these particles and features can be detected, identified, and compared.

The practical task then becomes searching for such particles and features, finding them, and finally conclusively identifying them. This is hardly trivial given their size, which may be unresolvable by stereomicroscopy alone. For example, microspheres of silica, used in many cosmetic formulations, are only a few 10s of micrometers in size. While not resolvable by stereomicroscopy, these isotropic spheres could be mistaken for an immiscible phase in a microscope slide preparation. Once found and recognized, they must be characterized to extract specific information about size, composition, and nano-morphology. Finally, the new questions of contamination, source, and significance arise in this new realm of materials. For example: Is this layer really a layer? When was this population of nanoparticles introduced? What is the potential for transfer? New, or at least more, vigilant checks for cross-contamination must be considered when working at these length-scales.

While some materials and the feature sizes are novel, the approach is in many ways a continuum of current practices, simply modified to work at increasingly higher resolutions. This presentation will explore the practical application of the approach discussed above through various casework examples from the realms of paint, fibers, cosmetics, dust, and soils to illustrate considerations relevant to the exploitation of increasingly smaller scales of trace evidence.

Ultimately, this study suggests that many existing methods common to most trace evidence laboratories can be better utilized to approach these smaller particles and features while other technologies in microanalysis are becoming (or have become) practical for application to this new realm of trace evidence.

Nanotrace, Microscopy, Trace Evidence

B148 The Investigation of Potential Mechanisms for the Formation of Postmortem Hair Root Bands: A Detailed Microscopical and Ultrastructural Analysis

*Jack Hietpas, PhD**, 1617 Courthouse Road, Stafford, VA 22554-5409; *JoAnn Buscaglia, PhD*, FBI Laboratory, CFSRU, 2501 Investigation Parkway, Quantico, VA 22135; *Adam H. Richard, MA*, FBI Laboratory, 2501 Investigation Parkway, Quantico, VA 22135; *Hilda S. Castillo, PhD*, 4401 Roland Avenue, Unit 107, Baltimore, MD 21210; *Stephen D. Shaw, MS*, FBI Laboratory, 2501 Investigation Parkway, Quantico, VA 22135; *Ernest J. Drummond, MS*, 1220 Blair Mill Road, Apt 209, Silver Spring, MD 20910; and *Joseph Donfack, PhD*, 2501 Investigation Parkway, Quantico, VA 22135

After attending this presentation, attendees will better understand the microscopical and ultrastructural changes associated with hair displaying a Postmortem Root Band (PMRB).

This presentation will impact the forensic science community by explaining how this research investigates potential mechanisms for the formation of PMRBs. These results may help establish a more scientifically rigorous framework in which to discriminate between hair with PMRBs and antemortem hair with similar microscopic characteristics.

A PMRB is a distinct microscopic feature that occurs in the pre-keratin region of anagen and early catagen hairs derived from deceased individuals.^{1,2} The appearance of this dark band has been shown to be the result of diffuse light scatter at the interface between the cells of the hair shaft and large elongated gas-filled void spaces.¹ The presence of these void spaces is the underlying basis for the observed PMRB.

The recognition of root banding in hair evidence can potentially provide valuable information concerning crime scene reconstructions; however, interpretations of PMRBs have recently been challenged in two high-profile criminal court cases.^{3,4} One of the underlying issues used to question the validity of interpreting hairs displaying PMRBs is that the mechanism of band formation is not known. To help shed light on this issue, several recent studies have investigated the potential to produce the characteristics of PMRBs in antemortem head hairs through various environmental conditions.⁵⁻⁸ Two of these studies report that some characteristics of PMRBs can be reproduced by environmental factors; it is cautioned that inexperienced hair examiners may falsely identify an environmentally degraded hair as a hair displaying a true PMRB.^{6,7}

The goal of this research is to investigate the potential mechanism for the formation of PMRBs. A better understanding of this mechanism is essential to establish a more scientifically rigorous framework in which to discriminate between hairs with PMRBs and antemortem hairs with similar microscopic characteristics. In this study, detailed observations were made using high-resolution images of ultramicrotome sections of head hairs with known PMRBs. Microscopical analysis of the banded regions indicate that the appearance of the PMRB is due to the degradation of the chemically and mechanically labile, non-keratin Intermacrofibrillar Matrix (IMM) in the pre-keratin region of anagen hairs. In addition, PMRB formation is confined to the cortex region of the hair shaft; there is no observable damage to the layers of the cuticle even at ~50,000x magnification.

In an attempt to further investigate potential mechanisms of PMRB formation, antemortem anagen head hairs were subjected to several conditions (e.g., pH series, protease digestions, buffer solutions) that may affect the IMM. The results from these *in vitro* studies indicate that some microscopic characteristics of PMRBs can be replicated. This is most readily demonstrated when anagen hairs are subjected to slightly alkaline (pH 7-8) aqueous ammonium salt solutions. The banding that forms in these hairs appears, at both the light microscope and scanning electron microscope scale, to be very similar to PMRBs. Ammonium and ammonia are viable causative agents because concentrations of these compounds increase rapidly in the decomposing body due to degradation of protein through various autolytic and bacterial processes.⁹ These results provide valuable insights that may assist in uncovering the mechanism for the formation of PMRBs.

Postmortem Hair Root Band, Hair Microscopy, Trace Evidence

B149 Analysis and Discrimination of Colored Pressure-Sensitive Tape Backing by Microspectrophotometry

Susan Gross, MSFS, 1430 Maryland Avenue, E, Saint Paul, MN 55106; and Josh Jorstad, BA, 1430 Maryland Avenue, E, Saint Paul, MN 55106*

The goal of this presentation is to present the results from a research project of absorbance microspectroscopy of red and blue pressure-sensitive tape backings.

This presentation will impact the forensic science community by showing the potential of Microspectrophotometry (MSP) as a method for differentiation of colored tape backings.

Tape is often used in the commission of a crime. Electrical tape can be used in improvised explosive devices while duct tape is often used to bind victims. Pressure-sensitive tape contains several components including, at minimum, an adhesive layer and a backing layer. A variety of colored and patterned tape backings is becoming more readily available. This variety of colors may offer another area of discrimination in the forensic analytical scheme.

MSP is the analysis of color in the visible range on a small scale. MSP is a well-accepted technique used in the analysis of trace evidence such as paint and fibers. Very little literature has been found on the MSP analysis of colored tape backings and no literature was found on how discriminating the MSP could be with tapes of the same color. The current study was performed to evaluate the usefulness of MSP to be used in conjunction with other analytical schemes in the forensic analysis of colored tape backings.

This study involved two different colors (red and blue) of pressure-sensitive tape in a variety of types (duct tape, electrical tape, and miscellaneous tape). Most tapes were purchased at local stores and were sold for general use. In this study, 18 red duct tape samples, 18 blue duct tape samples, 11 blue electrical tape samples, 8 red electrical tape samples, 12 red miscellaneous tape samples, and 5 blue miscellaneous tape samples were analyzed in this study.

The project was designed with the following objectives in mind: (1) to determine if the MSP could discriminate similar colored tape backing; (2) to determine if the MSP would add to the analysis scheme of physical characteristics and Fourier Transform Infrared (FTIR) analysis; and, (3) to determine the inter-variability of MSP results in a single roll of duct tape and electrical tape.

Tape samples were cross-sectioned using a microtome and analyzed using the CRAIC 20/20 PV™ MSP in replicates of five, minimally. Tapes were only compared within their same color and tape type groups and blind replicate samples were also included in the comparison groups. In addition, the same tape samples were evaluated based on physical characteristics (size, backing structure, adhesive color, and scrim, if applicable) and Infrared (IR) spectroscopy. The results of the discrimination of colored tape backings by MSP and how MSP adds additional discrimination to the traditional analysis scheme (physical characteristics and IR) will be discussed.

Duct Tape, Electrical Tape, MSP

B150 Quantitative Algorithm for Digital Comparison of Torn and Cut Duct Tape

Alicia Alfter, BS, 1332 Drake Drive, Apt C, Davis, CA 95616; William Ristenpart, PhD, University of California, Chem Engineering & Materials Science, One Shields Avenue, Davis, CA 95616; and Frederic A. Tulleners, MA, UC Davis, Forensic Science Graduate Program, 1909 Galileo Court, Ste B, Davis, CA 95618*

After attending this presentation, attendees will better understand minimizing human contextual bias via a quantitative imaging algorithm and corresponding mathematical methods to extract the edge profiles of torn and cut duct tape samples.

This presentation will impact the forensic science community by presenting information about a quantitative algorithm for the digital comparison of torn and cut duct tape.

The National Research Council (NRC) established a need at the national level for the validation of forensic science methods. Currently, duct tape end matching is based on human judgment with no quantitative criteria for identification. In this research, the needs of the forensic science community are met by minimizing human contextual bias with a quantitative algorithm. The detected edges of the exemplar and an arbitrarily large number of test samples are algorithmically subtracted from one another. The resulting residuals are then used to calculate the Sum of Squared Errors (SSE), a succinct metric that allows quantitative comparison of possible matches. A best or “most likely” match is determined by identification of the match with minimal SSE. The digital results are compared to a prior study of the same set of duct tapes that were visually assessed by a group of three researchers as part of an error determination study, thus providing a quantitative estimate of the respective error rates.

The MATLAB® software platform is used to code a series of mathematical functions in order to extract useful information from an image or a series of measurements. This research uses MATLAB® to obtain an edge profile of the duct tape image and performs analysis on the data. A digital image of the duct tape is collected using a high-resolution scanner at 1,200 Dots Per Inch (DPI). A digital profile of the tape is developed using the focused tear region and the parallel edges of the duct tape. The software performs a series of automated tasks. First, the software takes the selected image, sets threshold levels, and converts pixels to a binary image. Second, the software performs an ad hoc smoothing mechanism that removes the yarns by using a morphological operation that conducts erosion and dilation in order to remove the noise associated with the yarns. Last, the software converts the coordinate points into a graphical format and compares the edge profile to other edge profiles with a residual calculation that assesses the degree of difference along the focused tear region. The results are displayed on a bar and color map graph showing the difference of the SSE values for a matching piece of duct tape in comparison to the other duct tape pieces in the database. The user examines the residual calculations and determines whether one pair is quantitatively a better match than other pairs examined. The results establish that if other pairs of known matches have SSE values in the same range, it strongly suggests that it is the correct match. The duct tape database comprised of 2,200 paired duct tapes requires the analogies of 4,400 scanned duct tape images, making 19,360,000 inter-comparisons. Using this quantitative mathematical algorithm, the capability of the algorithm to identify matching specimens in sets of 200 duct tapes of a particular brand, to look at overall residue values by themselves as an indication of uniqueness, and to quantify the number of false positives and false negatives will be discussed. This study will compare and contrast the results with the findings of prior researchers who conducted a manual comparison of these same duct tape specimens. This prior study was presented at the 2011 American Academy of Forensic Sciences meeting by McCabe et. al.¹ The end product is a quantitative and statistically rigorous guideline for end-match comparison.

This research is funded by a grant from the Office of Justice Programs, National Institute of Justice award number # 2013-R2-CX-K009. The opinions, findings, and conclusions or recommendations expressed in this publication are those of the authors and do not necessarily reflect those of the Department of Justice.

Duct Tape, Physical Matching, Image Analysis

B151 Comparisons of Multivariate Preprocessing for Forensic Discrimination of Fibers by UV/Visible Microspectrophotometry

Stephen L. Morgan, PhD, University of South Carolina, Dept of Chemistry & Biochemistry, 631 Sumter Street, Columbia, SC 29208; and Nathan Fuenffinger, MS, 200 Atrium Way, Apt 615, Columbia, SC 29223*

The goal of this presentation is to present research studies to validate the forensic comparison advantages of first derivative preprocessing for comparison of Ultraviolet/Visible (UV/Vis) spectra of fibers. The effects of first derivative processing will be demonstrated with clear examples of improved discrimination between selected fibers and by improved classification accuracies using multivariate statistics.

This presentation will impact the forensic science community by illustrating how performing multivariate statistics on derivative spectra can improve discrimination of cotton fibers over other methods of spectral preprocessing for forensic comparisons. Significant increases in discrimination of fibers with mostly flat spectra with small changes in absorbance are possible using derivative spectra. Direct-dyed cotton fibers are one class of fibers that would seemingly benefit significantly from utilizing derivative spectra since these fibers tend to have distinctively low changes in absorbance. Although no single method of preprocessing is best for all types of spectra, the analyst must show caution when selecting cases in which derivatives should be used.

Determining which analytical method will have the highest discrimination power for trace evidence examinations is important to forensic laboratories in terms of allocation of time and resources. The importance of statistical methods for evaluation of trace evidence analysis in forensic science has also been of recent focus.¹

Color plays a critical role when analyzing natural fibers such as cotton in forensic investigations. UV/Vis Microspectrophotometry (MSP) is a non-destructive technique capable of providing objective color measurements on fibers in the form of absorption or transmission spectra; however, forensic fiber examinations can be hindered by spectra with little detail or points of comparison. Wiggins originally suggested that derivative preprocessing can enhance comparisons in UV/Vis spectra regard of cotton fibers.^{2,3} Although derivative preprocessing has been used for many years in analytical chemistry for the various applications described, it has not been widely utilized in forensic applications.^{3,4}

To validate this suggestion, multivariate classification on spectra of reactive, direct, and vat-dyed cotton fibers has been performed. These spectra were preprocessed using multiple methods including baseline correction, normalization, and first and second derivatives. Principal Component Analysis (PCA) followed by linear discriminant analysis (LDA) was employed to estimate classification accuracy.⁵ Direct-dyed fibers exhibited almost featureless and low-absorbing spectra compared to those of reactive and vat-dyed fibers. As a result, classification accuracies for direct-dyed fibers were lower than those calculated for reactive and vat-dyed fibers. The results of this study show that derivative spectra can significantly enhance classification accuracy when analyzing spectra with only subtle features such as those seen with direct-dyed cotton fibers. No single method was best for all classes of fibers in the study and the shapes and intensities of the curves are important when determining if derivative calculations are auspicious.

The generality of this conclusion was confirmed using UV/Vis spectra from more than 400 dyed textile samples of cotton, acrylic, nylon 6,6, and polyester. All spectra were subjected to first derivative preprocessing and classified using PCA/LDA. Leave-one-out cross validation was used to test the discrimination of fiber spectra in each color and polymer group. The high discriminating power of UV/Vis spectra for fibers was further validated by correct classification for 89.50% with this diverse group of spectra from four different textile classes.

Fibers, Spectra, First Derivative

B152 Development of a Microspectrophotometric Spectrum Database for Comparison of Casework Textile Fiber Samples to Motor Vehicle Interior Fabrics

Rees A. Powell, BSc, ChemCentre, South Wing, Bldg 500, Curtin University of Technology, Bentley, Western Australia 6112, AUSTRALIA; Colin R. Priddis, BS, Curtin University of Technology, ChemCentre, South Wing, Bldg 500, Bentley 6112, AUSTRALIA; Peter A. Collins, BSc, ChemCentre, South Wing, Bldg 500, Curtin University of Technology, Bentley 6112, AUSTRALIA; and John Coumbaros, PhD, ChemCentre, South Wing, Bldg 500, Curtin University of Technology, Bentley 6112, AUSTRALIA*

The goal of this presentation is to focus on a recent cold case investigation in Western Australia in which a textile fibers database was utilized for data interpretation and ultimately led to the discovery of potential links between fibers recovered from victims and motor vehicle interior fabric sources. This presentation will highlight the importance of the effective organization of large volumes of textile fiber data for forensic intelligence and evidentiary purposes and will include specific case examples.

This presentation will impact the forensic science community by illustrating the use of a casework fibers database containing motor vehicle interior fiber Microspectrophotometric (MSP) spectra as a powerful investigative tool. Victims of homicide are often transported in a motor vehicle prior to their death and/or prior to disposal of the body. Textile fibers recovered from motor vehicle interior fabrics may exhibit MSP spectra with characteristics unlike those of clothing fibers and may be used to link an offender, victim, or scene to a motor vehicle.

The database developed at ChemCentre is currently populated with more than 7,900 fiber samples, including approximately 900 samples from motor vehicle interior fabrics as well as casework and validation samples and other exemplar materials. The database allows the user to perform objective MSP spectral comparisons by calculating modified Pearson correlation coefficients and to visually compare images of fibers acquired via microscopy. The modified Pearson method of correlation was evaluated using repeat samples collected from more than 40 garments of various fiber types and by re-examining data from previously completed cases and proficiency trials.

An interpretation approach utilizing the database has been developed in response to an investigation which contained more than 4,400 fiber samples and no control garments. The requirement was to investigate potential links between multiple victims by searching for common sources of transferred fiber evidence. Therefore, fibers of any color or type were of potential evidentiary value. The database approach highlighted critically important fibers (those with close MSP spectral matches to large numbers of other fibers) and used these to form groups of fibers with corresponding properties. Groups were then confirmed via comparison microscopy (in brightfield and fluorescence modes). This approach eliminates the need to investigate each fiber individually and minimizes the number of comparisons required via comparison microscopy, allowing for efficient and effective handling of large fiber cases. The database has also been used for objective fiber comparison in routine casework in concurrence with standard fibers methodology.

It is envisioned that future development of the database methodology will include collation of casework fiber samples and the formation of large collections of exemplar materials (primarily motor vehicle interior fabrics) across jurisdictions.

Textile Fibers, Database, Microspectrophotometry

B153 Examination of Statistical Methods for Forensic Analysis of Highly Similar Absorbance Spectra From Textile Fibers

*Alejandra Flores**, 4223 Mendenwood Lane, Orlando, FL 32826; *Michael E. Sigman, PhD*, University of Central Florida, National Center for Forensic Science, PO Box 162367, Orlando, FL 32816; and *Andres D. Campiglia, PhD*, University of Central Florida, Dept of Chemistry, 4000 Central Florida Boulevard, Orlando, FL 32816

After attending this presentation, attendees will understand the application of objective statistical methods of analysis for the comparison of highly similar textile fibers using microspectrophotometry.

This presentation will impact the forensic science community by providing error rates for the methods described.

A question for fiber analysis with regard to forensic science is: can a Questioned (Q) fiber be associated with a Known (K) source or not? When the Q and K fibers exhibit obvious differences in physical, optical, and chemical characteristics, fiber discrimination by traditional methods is straightforward. Issues may arise when the Q and K fibers originate from highly similar sources which may lead to false non-discrimination decisions during analysis. The goal of this research is to investigate the rates of discrimination between fibers of sources that are highly similar in color. Principal Component Analysis (PCA) was utilized for dimension reduction since this study deals with large multivariate datasets. Discrimination was based on a combination of the score and orthogonal distances at a specified cutoff value.

The samples for this study originate from three different datasets. The first dataset consists of six 10-gram swatches purchased from and dyed on-site by a third party. The fabric samples include two identical swatches of nylon, two identical swatches of acetate satin, and two identical swatches of acrylic. The dyestuffs were chosen in pairs based on molecular structure. Dyes pairs include ACID BLUE (AB) 25 and 41, Disperse Blue (DB) 3 and 14, and Basic Green (BG) 1 and 4. Nylon swatches were dyed with AB 25 and 41, respectively; acetate satin swatches were dyed with DB 3 and 14, respectively; and acrylic swatches were dyed with BG 1 and 4, respectively. A total of ten fibers were sampled from different areas of each of the swatches, and 15 absorption spectra were collected from each fiber via microspectrophotometry. The individual spectra collected from each fiber were averaged. The second dataset consists of five commercially available blue acrylic yarns purchased from local craft retailers. Yarns that are visually similar with regard to color and shade were purchased. Two pairs of yarns shared the same brand name but were labeled as different shades of the same color as specified by the manufacturer. Dye composition information is unknown for the yarn samples. For the yarns, five fibers were sampled from each and 30 spectra were collected from each fiber.¹ Again, the individual spectra from each fiber were averaged. The third dataset consists of six 100% cotton denims purchased from local craft retailers. Again, dye concentration information for denim samples is unknown. From each of the denims, eight dyed fibers were sampled and 15 spectra were collected along the length of each fiber. Averaged spectra were calculated for each fiber.

Averaged spectra were subjected to PCA for dimensionality reduction. Either the number of Principal Components (PCs) that retain at least 95% of the variance of the original dataset or the first two PCs were kept for further statistical calculations. Hold-one-out cross validation comparisons were performed for this study with regard to same sample (within source) and different sample (between source) comparisons. When a Q spectrum is projected into the K principal component space a score value is calculated based on the score and orthogonal distance, the respective cutoff values, and an optimization parameter, γ , which ranges from zero to one. The Q spectrum is discriminated from the K spectra when the score value is greater than one.

Optimized results for the test swatches are as follows: same sample-7.5% discrimination; different sample-100% discrimination. Results for the yarns are as follows: same sample-16% discrimination; different sample-100% discrimination. Results for the denims are as follows: same sample-10.7% discrimination; different sample-76.5% discrimination.

B154 Identification of Artificially Aged Silk at the Molecular Level

*McKenzie Floyd, BA**, George Washington University, 725 21st Street, NW, Rm 107, Washington, DC 20052; *Christopher M. Rollman, BS*, George Washington University, 2100 Foxhall Road, NW, Somers Hall, L14, Washington, DC 20007; and *Mehdi Moini, PhD*, George Washington University, Dept of Forensic Sciences, 2100 Foxhall Road, NW, Washington, DC 20052

After attending this presentation, attendees will understand how molecular biomarkers can be used to determine the age of historical silk textiles; they will also gain insight into how these same biomarkers can be used to detect forgeries.

This presentation will impact the forensic science community by speaking to the importance of art forensics in the preservation of cultural heritage, the detection of forged artworks, and the need to further understand our history. Many museums' artifacts are composed of or contain proteinaceous materials such as silk, wool, parchment, wood, etc. The research presented focuses on the molecular biomarkers of natural ageing in museums' proteinaceous specimens and how to use these markers to identify the age or the authenticity of these artifacts. Among the examples discussed will be some of the Iranian Buyid textiles in the United States that contain a large amount of fake ancient silk.

Shortly after the 1925 excavation of a number of genuine silk articles at the Bibi Shahr-Banu site south of Tehran, Iran, the market was flooded with forged Bibi Shahr-Banu silk textiles. Museums in the United States and Europe bought many examples, both genuine and fake; later, the authenticity of many of the specimens was questioned, resulting in a decades-long controversy concerning Buyid silks. Today, many believe that a vast number of these artifacts are fake; however, since no scientific method was available, the claims on the forgery nature of these silks were mostly based on speculation rather than sound scientific methods. The purpose of the research presented is to develop molecular level biomarkers for scientific identification of bona fide silks and forgeries using separation, mass spectrometry, and proteomics.

The degradation of silk — both natural and artificially induced — has been studied using X-ray diffraction, Ultraviolet/Visible spectrometry, and Fourier transform infrared spectroscopy, among others. Mass spectrometry is an ideal technique for studies of the biomarkers of degradation at molecular levels. In addition, it is a highly sensitive technique which allows species identification as well as post-translational modifications of proteins at low microgram levels. The high sensitivity of mass spectrometry allows for the identification of biomarkers of aging with minimal effect to the artifacts, which is essential for the analysis of precious museums' artifacts. The molecular markers of natural aging and degradation of proteins studied for this research include racemization, deamidation, oxidation, truncation, and amino acid conversion. After comparing these biomarkers of aging for the Buyid silk samples, the physical and chemical methods that could have been used to produce the forged silk were studied. For example, it was observed that the Bibi Shahr-Banu forgeries yield unusually high levels of racemization, and this could hold true for other post-translational modifications; this is also currently under study.

This presentation will address how biomarkers can indicate age or forgery as proven by the study of genuine and forged textiles and by the re-creation of forgery methods. It is hoped that attendees will learn the importance of understanding such mechanisms in the preservation of culture and the detection of art crimes.

Silk, Forgery, Mass Spectrometry

B155 Frequency of Occurrence of Original Equipment Manufacturer (OEM) Automotive Refinishes Using the Paint Data Query Database

Diana M. Wright, PhD, FBI Laboratory Division, Chemistry Unit, Rm 4220, 2501 Investigation Parkway, Quantico, VA 22135; and Andria H. Mehlretter, MSFS, FBI Laboratory, Chemistry Unit, 2501 Investigation Parkway, Quantico, VA 22135*

The goal of this presentation is to provide a basis for determining the potential significance in observing an OEM refinish in automotive paint comparisons.

This presentation will impact the forensic science community by illustrating how awareness of the rate of occurrence of OEM refinishes will assist paint examiners in determining the strength that may be assigned to conclusions in comparative associations. The rate observed in 1,000 samples will be provided along with the number of OEM topcoats observed within each refinish, which can also affect significance.

In recent years, the Paint subgroup within the Scientific Working Group for Materials Analysis has attempted to develop language that would convey significance of association in comparative paint examinations. The strength of association in reporting a fracture match or the discrimination of paint chips with obvious differences in physical or chemical characteristics can be conveyed using relatively straightforward text. Likewise, the rationale for associating a standard four-layer OEM paint chip with a known vehicle(s) of corresponding layer construction and chemical compositions can be succinctly described as long as appropriate caveats are in place to alert the reader to the existence of other vehicles also painted in the same manner.

Within the extremes of identification and elimination and somewhat proximal to the confines of the “middle road,” there exists the circumstances of associations that may be considered stronger or weaker than the “norm.” An architectural refinish layer on an automotive paint chip would be unusual. The absence of primers in a partial layer system paint chip transfer would weaken the strength of association that could be conveyed. Within these further classifications, where would an analyst place the significance of association of an OEM refinish paint chip comparison between a known source and a questioned paint chip?

To address this circumstance, the frequency of occurrence of an OEM refinish must be considered as well as the number of layers of refinish that are present between the comparison samples. Moreover, the number of refinish layers that are permissible in an OEM repair should also be known.

To gain some knowledge of the frequency with which OEM repairs occur, the physical samples used to populate the Paint Data Query (PDQ) database were assessed for OEM refinishes. Approximately 1,000 samples representing model years 2000-2013 were microscopically examined. Samples containing refinish topcoat layers (e.g., clear/basecoat layers over a typical four-layer OEM layer system) were noted. Visual indicators of basecoat consistency included comparable appearance with respect to color, flake distribution in a metallic finish, number of layers (e.g., tri-coat finishes), relative layer thicknesses, and thickness uniformity across the layer. The clear coat layers of the first and last topcoats were then analyzed by Fourier Transform Infrared (FTIR) spectroscopy to confirm the consistency of an OEM binder formulation between these systems.

The frequency of occurrence results for this study were on par or lower than reported industry expectations or standards for OEM refinish of topcoat systems. Further, the greatest number of OEM topcoat repairs observed was one; however, up to three topcoat OEM refinishes were observed on vehicles by two different manufacturers. All manufacturers are not equally represented in PDQ and not all were represented in the population of OEM refinishes observed nor was the rate of OEM repair correlated to a particular plant or model.

This study was intended to highlight the need for interpretative statements in comparative examinations. While some comparisons of mass-produced manmade materials are straightforward, it is not uncommon to encounter samples that require further discussion to strengthen or weaken the degree to which the items may be considered to be “associated.” It is hoped this work will promote further discussion with respect to the inclusion of interpretative language in comparison reports.

OEM Refinishes, Interpretation, Paint Data Query

B156 Forensic Analysis of Hoax Powders Using Morphologically Directed Raman Spectroscopy

Andrew C. Koutrakos, MS, 29 Murray Avenue, Shelton, CT 06484; and Brooke W. Kamrath, PhD, University of New Haven, Forensic Science Dept, 300 Boston Post Road, West Haven, CT 06516*

After attending this presentation, attendees will understand the advantages of using Morphologically Directed Raman Spectroscopy (MDRS) for the identification of hoax powders commonly employed in white powder attacks. In addition, attendees will better understand MDRS and how it can benefit the forensic science community.

This presentation will impact the forensic science community by providing criminalists with a new analytical tool for the identification of white powders commonly used in fake bioterrorism attacks.

In the wake of the September 11th terrorist attacks, there was an influx of white powder events, both real and hoax, throughout the United States. The most infamous of these white powder events was the Amerithrax attacks in the fall of 2001 that left 17 people sick and five dead from anthrax sent via anonymous letters containing white powders. Since these attacks, the Federal Bureau of Investigation and the United States Postal Inspection Service have responded to thousands of white powder events. More often than not, the attacks do not contain any toxic materials and are carried out for the sole purpose of causing terror and damaging infrastructure. These fake bioterrorism agents consist of white powders that come from a variety of common commercial sources and can be blended to further complicate the analysis and identification of these samples.

Artificial sweeteners are commonly employed hoax powders. These blends are simple mixtures of a sweetening agent and bulking material. Sweetening agents are several times sweeter than a comparable amount of table sugar. Consequently, artificial sweeteners require a bulking agent or filler such as dextrose to increase the volume of the blend and to mitigate any undesirable taste brought on by the sweetening agent. Flour, chalk, table sugar, and other colorless powders are also commonly used in these attacks. In addition to the chemical differences of the sample, there are size/shape variations that can be used to differentiate the powders from one another at the particle level.

MDRS is an ideal tool for the investigation of suspicious white powders because it combines chemical identification with particle size and shape analysis. Raman spectroscopy is a useful technique in forensic science for determining molecular chemistry because it is rapid, reliable, does not require contact with the sample, and is non-destructive. Thus, Raman spectroscopic analysis is ideal for the analysis of suspicious white powders; however, the high volume of the filler in sugar substitutes has a tendency to drown out the Raman signature of the sweetening agent when doing a traditional bulk analysis, making detection of the sweetening agent and identification of the brand of sweetener impossible. Raman microspectroscopy can be used to overcome this by analyzing and identifying individual particles of the white powder. Particle morphology and size information are also valuable for differentiating artificial sweeteners that are mixtures of the same components. Automatic image analysis takes the subjective element out of the measurement of particle size and morphology. It also makes the process more rapid than counting and measuring the individual particles within a greater mixture. When Raman microspectroscopy is paired with automatic image analysis of the particles, physical and chemical information about the components of the mixture can be obtained which can be used for discrimination and brand identification.

This presentation details the use of MDRS for the analysis for hoax powders. MDRS can be used for analysis at the individual particle level, making it ideal for identifying compounds that are mixed with bulking agents or in a blend. MDRS is capable of comparing both the concentrations and identities of samples in addition to collecting data on size distribution of the particles. Individual size and shape distributions can also provide information based on excipient particles that could be used for source attribution. MDRS is a useful tool for the analysis of hoax powders at the particles level that enables criminalists to rapidly and reliably determine the composition of these mixtures to aid in the investigation of white powder attacks.

Morphologically Directed Raman, Particle Size Distribution, Hoax Powders

B157 Quantitative Mapping of Post-Blast Nitroglycerin Residues on Pipe Bomb Fragments Using Total Vaporization-Solid Phase Microextraction-Gas Chromatography-Mass Spectrometry (TV-SPME-GC/MS)

Dana Bors, BS, IUPUI, 402 N Blackford Street, Indianapolis, IN 46202; Darren A. Dixon, IUPUI, 402 N Blackford Street, Indianapolis, IN 46202; and John V. Goodpaster, PhD, FIS Program, IUPUI, 402 N Blackford Street, LD 326, Indianapolis, IN 46202*

After attending this presentation, attendees will understand the value of quantitating explosive residue on pipe bomb fragments. A new technique will be used for quantitation, TV-SPME-GC/MS, which has several advantages over other methods. The validity of residue distribution mapping will also be discussed.

This presentation will impact the forensic science community by outlining how quantitating explosive residue using a novel technique and diagramming its dispersal can be valuable to both crime scene investigators and laboratory analysts examining pipe bomb fragments. By knowing the concentration of residue components, the efficiency of analytical techniques can be optimized. This in turn will maximize throughput and evidence turnaround time. In addition, if the dispersal of residue indicates any trends, this information can heighten the understanding of the explosion process, such as the progression of deflagration.

Although residue from the explosive filler in a pipe bomb is routinely found on the post-blast container fragments, the amount of this residue is not quantified. The obvious reason for this is that the legal question at hand is identification of the explosive, not its concentration; however, there is value to understanding the distribution of explosive residue on device components and disseminating that knowledge to crime scene personnel and forensic analysts. In particular, such “residue mapping” would provide general guidance as to what fragments may be more likely to contain high levels of residue. Additionally, the distribution of residues would also shed light on the process by which the explosive filler deflagrates, resulting in the ultimate failure of the device container.

In this study, TV-SPME-GC/MS was used to identify nitroglycerin, diphenylamine, and ethyl centralite, which are components found in Double-Base Smokeless Powder (DBSP). Traditional headspace SPME involves a three-phase system consisting of the sample, either in solid or liquid form, the headspace, and the fiber; however, by completely vaporizing the sample, the partitioning between the liquid and headspace is eliminated, eliminating matrix effects and increasing sensitivity. Another benefit of this technique is minimal sample preparation — any solid and/or non-volatile components do not enter the headspace. Additionally, significantly higher volumes of liquid extracts can be analyzed as compared to liquid injection (e.g., 70 μ L). Prior to analysis, fragments were extracted under agitation using methylene chloride or acetone. Extracts were then transferred directly to SPME vials for analysis. SPME parameters were optimized using an experimental design with final values of 20 minutes for extraction time and 60°C for extraction temperature. This technique was applied to five devices constructed from galvanized steel pipes as well as three Polyvinyl Chloride (PVC) pipes, all filled with DBSP. Results indicate the majority of nitroglycerin was located on the endcaps for the galvanized devices, which correlates with the portion of the device that fails first during an explosion. On average, 1.0 \pm 0.7mg of nitroglycerin was recovered from the galvanized devices. According to manufacturer information, the nitroglycerin content in the DBSP used was between 4% and 40%. This indicates that DBSP is quite efficient, with less than 0.05% of the original nitroglycerin remaining on the container fragments.

SPME, Explosives, Nitroglycerin

B158 Assessing the Forensic Utility of Particle Morphometry for the Characterization of Aluminum Powders in Explosives

*Jack Hietpas, PhD**, 1617 Courthouse Road, Stafford, VA 22554-5409; *Joshua Dettman, PhD*, 2501 Investigation Parkway, Quantico, VA 22135; *Raleigh Parrott II*, 2501 Investigation Parkway, Quantico, VA 22135; and *JoAnn Buscaglia, PhD*, FBI Laboratory, CFSRU, 2501 Investigation Parkway, Quantico, VA 22135

After attending this presentation, attendees will better understand the strengths and limitations of morphometry as a method for the characterization and discrimination of aluminum fuels for explosive compositions.

This presentation will impact the forensic science community by discussing this pilot project that is the first published study to demonstrate the application of aluminum particle morphometry as a quantitative method for the characterization of explosives, which may provide valuable prosecutorial evidence as well as lead identification for forensic investigations.

Aluminum (Al) powder is commonly used in the pyrotechnics and explosives industries where it functions to increase the heat of explosion when mixed with other metallic powders, oxidizers, and explosive components.^{1,2} The performance of Al powder as a fuel for explosives depends on powder particle shape and grain size.² In addition, Al powder is widely used in the illicit manufacture of improvised explosive devices as well as improvised explosives.³ Detailed protocols for making and acquiring Al powder are widely available in the “underground” literature and numerous internet web pages.^{4,5} Very little technical knowledge and machinery is required for making Al powders that are of sufficient grade (i.e., particle size range) to be useful for producing explosive mixtures. Owing to the widespread use and the numerous methods for the production of Al powder, there is the potential for significant variability in particle morphology and size distribution. The goal of this research is to investigate the utility of particle morphometry using automated techniques as a metric to discriminate between samples of Al powder.

Approximately 30 samples of Al powders and pastes were acquired from known legitimate manufacturers, several seized explosive devices, and produced in-house from aluminum flake-containing commercial spray paint and by grinding Al foil. Several of the Al powder samples derived from the devices required isolation from the explosive physical mixtures; isolation involved simple water extraction, manual separation, or mild acetic acid digestion (to remove carbonates without digesting the Al particles). Powder samples were subsequently wet-sieved using disposable polyester mesh of nominal sizes 250 μ m, 100 μ m, 50 μ m, and 10 μ m in order to assess within sample variability of size fractions, as well as to produce microscope slide preparations of consistent thickness for imaging. Transmitted light microscope images of the Al powder particles were acquired; images were subsequently batch-processed using commercial image analysis software and customized code. Dimensional analysis was calibrated using a National Institute of Standards and Technology-traceable stage micrometer; polystyrene spheres of 100 μ m, 50 μ m, and 10 μ m were used as secondary standards to assess linear calibration. Each image was converted to a binary image and pre-filtered using a high-pass filter to enhance edge detection. The following metrics were measured for each particle within each image field of view: area, aspect ratio, perimeter, roundness, mean diameter, radii (maximum and minimum distance from particle centroid to edge), and radius ratio. The large multidimensional datasets were analyzed using commercial and open-source statistical packages. The results from several multivariate statistical methods will be presented.

Preliminary results from this pilot study show that commercially manufactured Al powders (flake and atomized spherical grains) have a significantly narrower particle size distribution than in-house-produced powders. In addition, the spherical nature of the known atomized melt samples allows for rapid recognition of an industrial-scale manufacturer. The results from this research will provide a foundation in which to investigate further the variability that occurs within and between manufactured Al powders over production timescales.

Aluminum Powder, Automated Image Analysis, Explosives

B159 Classifying Aged Explosives to Determine Source

*John A. Reffner, PhD**, John Jay College of Criminal Justice, 524 W 59th Street, New York, NY 10019; and *Pauline E. Leary, PhD, 1934 Bulls Head Road, Stanfordville, NY 12581*

After attending this presentation, attendees will understand how explosives recovered over the past 25 years from different regions of the world were characterized so that classification based upon source was achieved. Detection and identification of explosives and their residues are important functions that are routinely performed by forensic scientists in the field and in the laboratory. It has become important to extend the testing of these samples to include methods for determination of sample source. Determination of source may be important from an investigative perspective. This information may also be used in a court of law to classify or even individualize a sample.

This presentation will impact the forensic science community by describing the best method for testing these samples. Methods used to source explosives are different from methods used for identification. This presentation will discuss the methods and analytical approaches used, providing attendees with the background needed to effectively perform this testing in their laboratories.

Sourcing explosives is an important capability. Although identification of the explosive is necessary, in many instances, investigators are aware of the type of explosive used during a bombing very early in an investigation due to various on-scene indicators. In these instances, a more important role of the forensic scientist is to determine the source of the explosive. One way in which sourcing may be achieved is through the detection and identification of physical and chemical markers present in the sample. These markers may provide insight not only about the sample's manufacturing process, but also about the sample's history including source or origin and storage conditions. Determination of individuals or organizations responsible for providing explosives used will allow the investigator to successfully identify, apprehend, and adjudicate responsible parties.

In this study, explosives recovered from various bombings in the 1990s and 2000s were analyzed using various analytical methods. Classifications of these samples based upon chemical and physical markers present in the sample were performed. Taggants and other identifiers present in very low concentration (<0.1%) were detected and identified in samples that were more than 20 years old. Sampling and methods were evaluated and optimized so that a complete characterization and classification of each sample was performed.

The results of this research will be presented. Explosives analyzed include SEMTEX[®], dynamite, C-4, PENTEX[®], tetryl, and DETASHEET[®]. These explosives were from seizures in different regions of the world. Methods including light microscopy, infrared spectroscopy, Raman spectroscopy, and gas chromatography/mass spectrometry will be covered. Method features and limitations will be discussed.

Explosives, Taggants, Sourcing

B160 Smokeless Powders Database at the National Center for Forensic Science

*Dana-Marie K. Dennis, BS**, 6480 Ranelagh Drive, Unit 102, Orlando, FL 32835; *Jessica L. Frisch-Daiello, PhD*, 5550 E Michigan Street, #1321, Orlando, FL 32822; *Mary R. Williams, MS*, PO Box 162367, Orlando, FL 32816-2367; and *Michael E. Sigman, PhD*, University of Central Florida, National Center for Forensic Science, PO Box 162367, Orlando, FL 32816

The goal of this presentation is to develop an internet-accessible database comprised of analytical data for smokeless powder samples of the commercially available single-base and double-base designations.

This presentation will impact the forensic science community by providing a demonstration of the database which contains several hundred records of smokeless powder samples which are currently, or were previously, available for purchase.

Smokeless powders are low-explosive propellants in military and civilian ammunition which are commonly used in pipe bombs and other improvised explosive devices. There are three types of smokeless powders, namely single-base, double-base, and triple-base. The smokeless powders are distinguishable based on their primary energetic materials. Single-base powders contain nitrocellulose as their primary energetic material; double-base powders contain nitroglycerin in addition to nitrocellulose, and triple-base powders contain nitroguanidine in addition to nitrocellulose and nitroglycerin. In each powder type, there are a number of additional constituents which function as plasticizers, stabilizers, opacifiers, flash suppressants, and deterrents. The smokeless powders are available in a variety of shapes, namely: ball, flattened ball, cylinder (tubular), disk, and lamel. Of the three types, single- and double-base powders are readily procured from sporting goods retailers.

In 2009, the National Center for Forensic Science (NCFS) in collaboration with the Explosives Committee of the Scientific/Technical Working Group for Fire and Explosions developed the smokeless powders database which consists of a compilation of data generated from the analysis of the commercially available smokeless powder samples using techniques such as stereomicroscopy, Fourier Transform Infrared (FTIR) spectroscopy, and Gas Chromatography/Mass Spectrometry (GC/MS). The database is comprised of smokeless powder data contributions from a number of sources including NCFS, the Federal Bureau of Investigation, and the Netherlands Forensic Institute. The database contains physical and chemical descriptions of the powders including powder morphology (shape), dimensions, distinguishing features, and the main chemical components for each sample record. The database is searchable by the physical and chemical parameters and returns a list of potential candidates including source information, micrographs of the powders and bulk sample containers, physical measurements, and GC/MS and Attenuated Total Reflectance (ATR)/FTIR data.

The National Institute of Justice recently awarded funds to NCFS for the purchase and analysis of smokeless powders and the subsequent upload of their analytical data. The newly acquired samples will also be distributed to a number of American Society of Crime Laboratory Directors-accredited laboratories as a reference collection. In addition, the explosives committee which oversees maintenance of the database is receptive to contributions of smokeless powder data from national and international sources. The database serves as a resource for law enforcement agencies and will aid in the characterization, classification, and comparison of smokeless powder samples.

This work was supported in part by the National Institute of Justice, Office of Justice Programs, award 2013-R2-CX-K008. The content of this publication does not necessarily reflect the position or the policy of the United States government, and no official endorsement should be inferred. Smokeless Powders Database, Single-Base, Double-Base

B161 Odorant Measurements and New Materials for Canine Training

William A. MacCrehan, PhD*, Stop 8392, Gaithersburg, MD 20899; Matthew E. Staymates, MS, National Institute of Standards and Technology, 100 Bureau Drive, Mail Stop 8371, Gaithersburg, MD 20899; Stephanie Moore, MFS, Department of Forensic Sciences, 2036 H Street, NW, Washington, DC 20052; and Michele Schantz, PhD, NIST, Stop 8392, Gaithersburg, MD 20899

The goal of this presentation is to bring scientific rigor to canine training through measurements and training aid materials.

This presentation will impact the forensic science community by explaining how training aid materials were devised that provide the scent profile of real explosives and how this may improve court acceptance of forensic working dog evidence.

Canines achieve very high sensitivity for detecting military and improvised explosives using the volatile signatures of these materials. Solid-Phase Microextraction (SPME) coupled with techniques such as Gas Chromatography/Mass Spectrometry (GC/MS) is typically used for analysis of such vapor profiles; however, SPME/GC/MS measurements suffer from irreproducibility as a result of fiber-to-fiber absorptive differences as well as drift in the absorptive capacity and MS detector response. This limits the potential to characterize equitably the vapor profile of different samples or monitor the vapor-time profile of a given sample. The National Institute of Standards and Technology (NIST) has introduced an approach that permits the reliable characterization of the vapor profile of a sample relative to the saturated headspace of the target analyte. To achieve reproducibility, the SPME fiber will first sample from an “internal standard” and then sample the test or calibrant sample. This approach, Solid-Phase Microextraction/Externally Sampled Internal Standard (SPME/ESIS), improves the reproducibility of SPME/GC/MS by more than an order of magnitude.¹ SPME/ESIS has been applied to determine the vapor-time profile of a number of explosives, volatile components in explosives formulations, and as a screening tool for the development of training aid materials for canine detection.²

A particularly promising approach to training aid fabrication is “infusing” the volatile components of explosives into a polymer matrix (Polydimethylsiloxane (PDMS)). This approach provides a reliable vapor release and renders explosives inert. Infusion and vapor release were tested for Triacetone Triperoxide (TATP) (an improvised explosive), 2-ethylhexanol (a plastic explosives odorant), and 2,4-dinitrotoluene (DNT) (the volatile odorant in TNT). The results for a simulated training aid for DNT is shown in the figure. After a short induction period, constant release of the DNT from the infused PDMS (pink trace) was demonstrated over 70 hours using the SPME/ESIS technique by the consistency of the A/E ratio.

Infusing the odors of TATP, Composition C-4, and Semtex into PDMS is also providing promising results for canine detection. Bomb dogs trained on these explosives alert 80% to 100% of the time when presented with the infused PDMS simulants.

The design of the training aid container using a novel simulated canine nose has also been evaluated. This anatomically-correct nose “sniffs” with the known velocities of large dogs. A means of capturing and analyzing the collected odorant is also incorporated into the system, permitting a quantitative measure of the performance of the training aid design.

The Department of Homeland Security Science and Technology Directorate funded the production of the work presented in this material under HSHQPM-13-X-00048 with the National Institute of Standards and Technology.

B162 Modern Challenges in Fire Debris Analysis

*Jamie M. Baerncopf, MS**, 355 N Wiget Lane, Walnut Creek, CA 94598; and *Katherine D. Hutches, PhD, ATF*, 355 N Wiget Lane, Walnut Creek, CA 94598

After attending this presentation, attendees will understand current issues faced by fire debris chemists. This will include issues classifying ignitable liquids, identifying matrix interferences, non-routine analysis, and incendiary devices.

This presentation will impact the forensic science community by serving to help fire debris chemists identify issues they may face in more complex casework.

There has been extensive literature addressing the challenging nature of fire debris analysis. This presentation serves as a continuation and expansion of the literature by providing several examples of such challenges encountered during research or casework. The range of current issues faced by fire debris examiners is vast and extends to neat liquids, debris or matrix effects, and other non-routine samples. Though the majority of liquid samples encountered in the analysis of ignitable liquids are easily identified, some liquids are difficult to classify using the widely recognized and accepted American Society for Testing and Materials classification protocol. This presentation provides several examples of such liquids. Additionally, the presentation examines the variations observed in the alkane, indane, and polynuclear aromatic content among several geographically diverse gasoline samples. Another issue addressed in this presentation, which has been discussed previously in the fire debris community, are the limitations in identifying specific products. These limitations is due both to the change in formulation of a product over time as well as different products with nearly identical chemical compositions. These limitations should be considered in cases where an investigator requests the identification of a specific source of an ignitable liquid beyond the ignitable liquid class.

Matrix effects of further concern to the fire debris examiner include inherent petroleum products and microbial degradation. These two issues have been previously studied in the literature; however, this presentation expands on both. Inherent petroleum products are widespread and should be well understood by all fire debris chemists. As such, several examples are reviewed such as isoparaffinic products in various plastic products, limonene in tires, and gasoline in shoes.

In recent years, fire debris chemists have become increasingly responsible for additional analyses, which may require alternative sample preparation techniques and instrumentation. Among these analyses are alternative fuels such as E85 and biodiesel, vegetable oils, lubricating oils, and petroleum greases. Alternative fuels can typically be identified using general fire debris analytical procedures and their prevalence in casework is increasing. Vegetable oils may be of interest due to the propensity of some oils to self-heat and potentially cause ignition of surrounding fuel. Analysis of vegetable oils requires conversion of the fatty acids in the oil to methyl esters and analysis by a Gas Chromatograph/Mass Spectrometer (GC/MS) equipped with a specific column not commonly used for ignitable liquid analysis. Lubricating oils and petroleum-based greases are an extension of petroleum-based ignitable liquids, but much less volatile. These products may be identified using a standard GS, but can be further characterized, and possibly compared, using a high-temperature GS.

Unconventional ignition methods are often incorporated into improvised incendiary devices and as such are very wide ranging. Some examples that have been encountered include flares, thermite mixtures, and improvised napalm. These types of analyses typically require additional instrumentation outside of the typical GC/MS such as infrared spectrometry, X-ray powder diffraction, and scanning electron microscopy. This presentation hopes to provoke discussion of these various issues as it is important to keep an open dialog among current fire debris examiners.

Fire Debris, Ignitable Liquids, GC/MS

B163 The Effects of Burning and Mold Growth on the Analysis of Fire Logs

Kelsey R. Winters, BS, 1135 Colonel Joshua Court, Westminster, MD 21157; and Michelle Evans, MSFS, Bureau of ATF, 6000 Ammendale Road, Beltsville, MD 20705-1250*

After attending this presentation, attendees will better understand the different fuel types in fire logs and the effects burning and mold growth will have on extraction, analysis, and comparison.

This presentation will impact the forensic science community by raising awareness of the change in fuel type of many fire logs from petroleum-based waxes to vegetable oils. This change in fire log composition means that different methods must be used to analyze fire log evidence, specifically the extraction method and instrument parameters. Fire debris analysts who receive fire log samples will also need to take into consideration the effect fire and mold growth have on the composition of the logs.

Artificial fire logs have become a popular substitute for wood to burn in fireplaces due to the fact that they are readily available, easier to light, and will burn unattended for longer periods of time. These fire logs are typically manufactured by combining a cellulosic material, such as sawdust or wood particles, with a combustible binder. The binder or fuel typically has been a petroleum (paraffin) wax; however, in recent years, many manufacturers have switched to using vegetable oils instead of petroleum waxes. While research has been published regarding vegetable oils and spontaneous ignition as well as the analysis of fire logs containing petroleum-based waxes, none has yet been published concerning the analysis of vegetable oils in fire logs.

Vegetable oils are primarily composed of triglycerides, which consist of three fatty acids attached to a glycerol backbone. The fatty acids in vegetable oils are typically unsaturated straight chains consisting of an even number of carbon atoms. Fatty acids are not well-resolved on a typical fire debris non-polar column but can be derivatized into methyl esters and analyzed on a polar column for best separation.

The Bureau of Alcohol, Tobacco, Firearms and Explosives laboratory received evidence from a case in which it was suspected that a fire log was used to initiate a fire. Numerous samples contained vegetable oil-based fuels and exhibited mold growth. Microbial degradation of petroleum products in soil and building materials has been reported. This degradation makes the classification of the petroleum products nearly impossible. Although the vegetable oil-based fuel in the case samples could be identified, apparent microbial degradation made the comparison of questioned and known samples more difficult.

This study was designed to determine the effects that both burning and mold growth have on the composition of the fire log. A total of 34 fire logs, varying in brand and type, were cut into approximate thirds. One third were analyzed intact and served as the clean, unburned sample. One third were burned until charred, extinguished by smothering the flame, and subsequently analyzed. The final third were burned until charred, extinguished with water, and stored in metal cans outdoors for a month in order to allow mold growth before analysis.

The fire logs were extracted in pentane and the extracts were analyzed by High Temperature Gas Chromatography-Mass Spectrometry (HTGC/MS) to identify any petroleum-based waxes present. The same pentane extract was then derivatized using a base-catalyzed reaction to form Fatty Acid Methyl Esters (FAMES) and run on a GC/MS with a column specific for FAMES in order to determine whether the fuel contained vegetable oils. GC/MS data of the intact fire logs indicated that a majority contained petroleum-based waxes and vegetable oils, thus requiring the use of both instruments. Chromatographic differences in the petroleum and FAME compositions of the intact, burned, and burned/molded samples were documented through visual comparisons and peak area ratios. While petroleum waxes appeared unaffected by fire and mold, vegetable oils showed significant changes in composition.

Fire Logs, GC/MS, Vegetable Oils

B164 Investigation of Body Products on Worn Clothing Found at a Fire Scene Conflicting With Ignitable Liquid Residue Identification by Gas Chromatography/ Mass Spectrometry (GC/MS)

*Gina Guerrero, BS**, 784 Monroe Turnpike, Monroe, CT 06468-1962; *Erika Chen, MS*, 6254 97th Place, Apt 7E, Rego Park, NY 11374; *Michael Valetutti, MS*, Little Neck, NY; and *Brooke W. Kammrath, PhD*, University of New Haven, Forensic Science Dept, 300 Boston Post Road, West Haven, CT 06516

After attending this presentation, attendees will be aware of the chemical interferences caused by body products on worn clothing and the associated difficulties with classifying Ignitable Liquid Residues (ILRs) using GC/MS.

This presentation will impact the forensic science community by informing fire debris analysts about the extent of the interference to the identification of ILRs that is caused by body products on worn clothing and how it can cause misinterpretations and misclassifications.

The question of whether cosmetic and medicinal body product deposits on clothing as well as the composition of clothing are being mistaken for ignitable liquids is of considerable importance for criminalists in forensic science laboratories. This research investigated the magnitude of the impact that body products (such as body oil, moisturizers, and perfume) on worn clothing have on ILR identification in fire debris. Body products can have similar chemical profiles to ignitable liquids as a result of comparable chemical compounds that are found in both sources. Consequently, body products on worn clothing could potentially cause difficulties for practitioners when classifying ILRs present in fire debris according to the American Society for Testing and Materials (ASTM) method E1618 (“Standard Test Method for Ignitable Liquid Residues in Extracts from Fire Debris Samples by Gas Chromatography/Mass Spectrometry”).

Worn clothing samples of varying fiber content (cotton, polyester, lycra-spandex, and a blend) were collected from three individuals who had applied a body product provided for them before wearing the clothing item. The clothing was worn over a period of 12 hours, prior to collection. Passive headspace concentration by Activated Charcoal Strips (ACS) was performed according to ASTM method E1412 (“Standard Practice for Separation of Ignitable Liquid Residues from Fire Debris Samples by Passive Headspace Concentration With Activated Charcoal”), heating the cans at 80°C for 16 hours followed by desorption of the ACS with carbon disulfide (CS₂). The samples were then analyzed by GC/MS with a quadrupole mass analyzer and the chromatograms were evaluated as to whether the residues could be misidentified as belonging to a class of ignitable liquids.

A preliminary study was performed prior to conducting the experiment with human subjects. It consisted of subjecting various body products to the ASTM E1412 and E1618 analytical methods. Results from the analysis of the neat samples showed that several body products could be mistaken for ILRs. Some products had chromatograms that showed similar visual patterns to ignitable liquids but showed differences in the mass spectral peak identifications. The results of this preliminary study were used to select the body products used in the human trials. In addition, unworn clothing samples were analyzed and the resulting chromatograms revealed compounds that could also cause difficulties with ILR classification. Additionally, it was found that materials used to preserve the clothing should not be ignored. These results highlight the complexities involved with identifying ILRs by demonstrating both the possible misclassifications and masking of ILRs that can occur due to the interference of body products and clothing.

This research has important implications for criminal justice because the identification of an ILR on clothing could result in an innocent person being charged with an arson crime or, in contradiction, present misleading data that would allow the guilty to walk free. Thus, it is critical to be able to differentiate interfering substances on substrates from ILRs when analyzing fire debris.

Fire Debris, Ignitable Liquids, Substrate Contribution

B165 Identification of Triglycerides in Pristine and Degraded Vegetable Oils and Fats in Fire Debris Extracts by Liquid Chromatography/Mass Spectrometry

Craig M. Bryant, MSc, Centre of Forensic Sciences, 25 Morton Shulman Avenue, Toronto, ON M3M 1J8, CANADA; and Josie Warnica, MSc*, Centre of Forensic Sciences, 25 Morton Shulman Avenue, Toronto, ON M3M 1J8, CANADA*

After attending this presentation, attendees will understand a novel application of Liquid Chromatography/Mass Spectrometry (LC/MS) to the forensic analysis of vegetable oils and fats in fire debris samples.

This presentation will impact the forensic science community by presenting an LC/MS technique that will provide a method for directly identifying triglycerides in fire debris extracts without prior derivatization. Triglycerides are the principle components of vegetable oils and fats. Identification of triglycerides was found to be possible for vegetable oils and fats that had been used for cooking and/or exposed to fire conditions.

Triglycerides are the principle components of vegetable- and animal-based oils and fats. Analysis for triglyceride-based oils and fats provides valuable information in a range of fire investigation scenarios, including kitchen fires, household fire deaths, and cases of spontaneous combustion that involve oily rags.

As triglycerides are large molecules that are not sufficiently volatile to be analyzed directly by GC-MS, many laboratories derivatize triglycerides extracted from fire debris to their corresponding Fatty Acid Methyl Esters (FAMES). FAMES are readily separated and identified by GC/MS. In October 2013, the American Society for Testing and Materials (ASTM) International published a new standard test method for "Extraction and Derivatization of Vegetable Oils and Fats from Fire Debris and Liquid Samples with Analysis by Gas Chromatography/Mass Spectrometry" (ASTM E2881-13). Unfortunately, it is not possible to specifically confirm the presence of cooking oils and fats using this method as resulting FAMES may originate from free fatty acids in the substrate and not from triglyceride-based oils and fats. The ASTM test method specifically cautions about forming this conclusion in section 4.2.1.

In order to confirm the presence of vegetable oils and fats, a method is needed that allows separation and identification of mixtures of intact triglycerides in fire debris extracts. Analysis of triglycerides by Liquid Chromatography-Mass Spectrometry (LC/MS) has been widely reported in food industry publications; however, these studies typically focus on pristine/unused cooking oils. In fire debris samples, cooking oils may be degraded by exposure to air, usage in cooking, and exposure to fire conditions. The purpose of this study was to determine whether or not mixtures of triglycerides could still be identified in fire debris extracts after the vegetable oils and fats had been used for cooking and/or exposed to fire conditions.

A total of 48 vegetable- and animal-based oils and fats were purchased at local supermarkets, including multiple brands of each type of oil or fat wherever possible. Each of these products was analyzed in their pristine state by LC/MS using Multiple Reaction Monitoring (MRM). Representative samples of each of these oils and fats were then placed in clean, unlined paint cans and heated with a Bunsen burner to their: (1) smoke point; (2) non-piloted ignition point; and, (3) self-extinguishment point. This was based on a method developed by the State of Florida Bureau of Forensic Fire and Explosives Analysis. Each of these burns was completed for neat liquids and liquids spiked onto cotton fabric or wood. Resulting residues were extracted with hexane and analyzed by LC/MS using MRM. Four oils with high smoke points (canola, peanut, soybean, and sunflower) were further subjected to six deep-fry cooking cycles using a commercial deep fryer. These cooked oils were subsequently analyzed by LC/MS to determine the effect of cooking. Cooked oils were then burned as per the method described above to determine the effect of fire conditions on oils that had previously been used for cooking.

Mixtures of four or more triglycerides were readily identified using LC/MS in all samples that had undergone cooking and/or burning. Differences in triglyceride peak ratios were minimal, and in many cases the degraded oil was indistinguishable from pristine/unused oils. In samples where peak ratio differences were observed, more degradation was observed on the more highly unsaturated triglycerides.

As mixtures of multiple triglycerides remained identifiable in all degraded samples in this study and the peak ratios of degraded samples were similar to pristine/unused oils, LC/MS analysis of triglycerides has been demonstrated to be an effective and reproducible method for the identification of cooking oil residues in fire debris extracts.

Vegetable Oils and Fats, Triglyceride Analysis by LC/MS, Fire Debris

B166 Analysis of Arson Fire Debris by Low Temperature Dynamic Headspace Adsorption Porous Layer Open Tubular (PLOT) Columns

Thomas J. Bruno, PhD*, National Institute of Standards and Technology, 325 Broadway, Boulder, CO 80305; Tara M. Lovestead, PhD, NIST, 325 Broadway, Boulder, CO 80305; Jessica Nichols, BS, NIST, 325 Broadway, Boulder, CO 80305; and Megan Harries, BS, NIST, 325 Broadway, Boulder, CO 80305

After attending this presentation, attendees will have an understanding of: (1) the general metrology of PLOT-cryoadsorption (cryo); (2) the advantages of PLOT-cryo for fire debris sampling; (3) the ability to use PLOT-cryo in the field; and, (4) the use of high throughput PLOT modules for rapid analyses.

This presentation will impact the forensic science community by providing familiarity with the evolving scope of application afforded by PLOT-cryo.

Many Ignitable Liquids (IL) can be used to start an arson fire, the most common being gasoline, diesel fuel, kerosene, charcoal lighter fluid, paint thinners, and solvents; however, many less-common fuels have been used as well. Attention is even being paid to the new alternative fuels such as biodiesel fuel as potential ILs. Forensic scientists must routinely identify and characterize the accelerant or IL in a credible, defensible manner. The analysis of fire debris for the presence of residual IL has long been an accepted and routine aspect of arson investigations and the techniques available for such analyses have evolved. The nature of ILs as multi-component, moderately volatile fluids makes Gas Chromatography (GC) the most important and widely used method for fire debris analysis and the majority of liquid residue analyses performed in forensic laboratories utilize GC with some combination of detectors and peripherals. The most common is GC with mass spectrometry as the detector. In practice, the use of a single quadrupole mass filter is most common; however, tandem mass spectrometric methods have been used as well. Once presented to the instrument, the analysis of a sample is usually straightforward. There is a challenge in rapidly and reliably obtaining a sample for analysis from the vapor headspace of fire debris collected at the scene.

In this presentation, results of the application of PLOT-cryo to the analysis of ignitable liquids in fire debris are presented.¹ This study tested ignitable liquids, broadly divided into fuels and solvents (although the majority of the results that will be presented were obtained with gasoline and diesel fuel) on three substrates: douglas fir, oak plywood, and nylon carpet. It was determined that PLOT-cryo allows the analyst to distinguish all of the ignitable liquids tested by use of a very rapid sampling protocol and performs better (more recovered components, higher efficiency, lower elution solvent volumes) than a conventional purge-and-trap method. This study also tested the effect of latency (the time period between applying the ignitable liquid and ignition) and tested a variety of sampling times and a variety of PLOT capillary lengths. Reliable results can be obtained with sampling time periods as short as three minutes and, on PLOT capillaries, as short as 20cm. The variability of separate samples was also assessed, a study made possible by the high throughput nature of the PLOT-cryo method. It was also determined that the method performs better than the conventional carbon strip method that is commonly used in fire debris analysis. Variations of the PLOT-cryo method to provide for high-sample throughput and portable operation in the field will also be described.²⁻⁵

PLOT-Cryoadsorption, Fire Debris, Ignitable Liquids

B167 Application of Likelihood Ratios in Fire Debris Analysis

Michael E. Sigman, PhD*, University of Central Florida, National Center for Forensic Science, PO Box 162367, Orlando, FL 32816; and Mary R. Williams, MS, PO Box 162367, Orlando, FL 32816-2367

The goal of this presentation is to discuss a statistical approach to classification of fire debris as positive or negative for the presence of ignitable liquid residue and the determination of a likelihood ratio for the two competing hypotheses. Conversion of the likelihood ratio to a verbal scale expressing support for one hypothesis relative to the other will also be discussed.

This presentation will impact the forensic science community by showing the benefit of exposure to concepts that are fundamental to the evaluation of forensic evidence.

Likelihood ratios can be understood in the framework of receiver operating characteristic curves, probability density distributions, and Bayesian decision theory. A likelihood ratio allows the forensic scientist to evaluate evidential value under two competing hypothesis in the absence of information regarding prior probabilities, which are often unavailable. The magnitude of the likelihood ratio can be converted to a verbal scale that expresses the strength of evidential support for the two competing hypotheses. Evett has proposed a verbal scale of support as defined by the following terms on the indicated likelihood ratio intervals: “none” (0, 1); “limited” (1, 10); “moderate” (10, 100); “moderately strong” (100, 1,000); “strong” (1,000, 10,000); and, “very strong” (>10,000).¹ In the event that prior probabilities are available, posterior odds can be determined.

One example that demonstrates these concepts is the classification of fire debris as positive or negative for the presence of ignitable liquid residue. The likelihood ratio under the hypothesis that a sample is positive (H+) or negative (H-) for ignitable residue, given some Evidence (E), is defined as the ratio of class-conditional probabilities — $P(E|H+)/P(E|H-)$. The underlying statistical model is based on a set of extracted ions from total ion spectra of ignitable liquids.² The total ion spectra for ignitable liquids and substrate pyrolysis products were taken from the Ignitable Liquids Reference Collection and the Substrates Database and computationally mixed to produce a balanced set of 3,000 total ion spectra for samples that were defined to be positive or negative for ignitable liquid residue.³ Principal component analysis was performed on the data set for feature extraction and a support vector machine with radial kernel function was trained on the resulting scores and tested by ten-fold cross validation with 20% hold-out.

As a hard classifier, the optimum model had a cross-validation accuracy of 90% (i.e., 275 of 300 ignitable liquid samples were correctly classified and 262 of 300 substrate samples were correctly classified). The probabilities of class membership were obtained from the support vector machine model using a flat prior probability and the strength of support for the competing hypotheses was determined from the likelihood ratio. Using Evett’s verbal scale, of 300 ignitable liquid containing samples, the likelihood ratio for one sample showed strong support for the presence of ignitable liquid residue, 36 showed moderately strong support, 143 showed moderate support, 95 showed weak support, and 25 showed no support. Using the same verbal scale, of 300 substrate samples, the likelihood ratio for three samples showed moderate support for the presence of ignitable liquid residue, 35 showed weak support, and 262 showed no support. Results from further testing with other models will also be reported.

This project was supported in part by Award No. 2009-DN-BX-K227 awarded by the National Institute of Justice, Office of Justice Programs, United States Department of Justice. The opinions, findings, and conclusions or recommendations expressed in this publication/program/exhibition are those of the author(s) and do not necessarily reflect those of the Department of Justice.

Fire Debris, Likelihood Ratio, Statistics

B168 Detection and Quantitation of Polydimethyl Siloxane Using Liquid Chromatography/Mass Spectrometry

Katherine Ann Schilling Fahnestock, BS, California Institute of Technology, Dept of Chemistry, M/C 101-20, Pasadena, CA 91125; Derek Dorrien, MS, 4930 N 31st Street, Forest Park, GA 30297; Anna L. Deakin, MS, Defense Forensic Science Center, 4930 N 31st Street, Forest Park, GA 30297; and Danielle Green, BS, 9306 Paces Park Drive, Decatur, GA 30033*

After attending this presentation, attendees will understand and be able to implement a method for the detection and quantitation of Polydimethyl Siloxane (PDMS), a common condom lubricant.

This presentation will impact the forensic science community by providing a successful validation that can result in a more robust and comprehensive analysis of chemical extracts which contain PDMS.

This presentation will cover a validation study for the use of a new methodology in the analysis of forensic samples related to sexual assault investigations. This successful validation will result in a more robust and comprehensive analysis of chemical extracts which contain PDMS.

Examination of items of evidence from sexual assault crimes may in some instances require the detection and comparison of materials from condoms and sexual lubricants used in the commission of the crime. Improvements in the ability to detect and discriminate these types of materials can lead to more effective processing of sexual assault casework. A common condom lubricant, PDMS, is a very stable polymer with several potential sources including, but not limited to, lotions, cosmetics, machining greases, and lubricants. As such, trace amounts of PDMS may be present on items of evidence from environmental contamination. Typical analyses targeting PDMS are qualitative in nature and do not allow for the discrimination of trace background levels from more concentrated lubricant stains.

The quantitative analysis of PDMS was conducted by normal phase Liquid Chromatography/Atmospheric Pressure Chemical Ionization-Mass Spectrometry (LC/APCI-MS) with Multiple Reaction Monitoring (MRM). LC/APCI-MS (MRM) analysis (limit of detection $1.7\text{ ng } \mu\text{L}^{-1}$; limit of quantitation $3.5\text{ ng } \mu\text{L}^{-1}$).

Cuttings from a collection of new and well-worn underwear were analyzed by this method to establish the expected background levels of PDMS in garments. The global average background concentration of PDMS in new and freshly washed but unworn undergarments was determined to be $6 \pm 5\text{ } \mu\text{g cm}^{-2}$. A sampling of well-worn and washed men's and women's undergarments yielded a global average PDMS concentration of $4 \pm 2\text{ } \mu\text{g cm}^{-2}$.

PDMS concentrations in a variety of lotions, condoms, and personal lubricants were determined to assess the contribution of each product to a potential stain or background. All lotions studied here were found to contain less than 1.0% PDMS by mass. Condom residue varied in composition based on lubricant type; spermicidal and unlubricated condoms did not typically contain PDMS. Condoms labeled as lightly lubricated were nearly 100% PDMS by mass. The average for other lubricated condoms was 29% PDMS by mass, but ranged from 10% to 50% PDMS by mass. Only one personal lubricant studied here was found to contain PDMS (41% by mass).

The findings from this study show that underwear background PDMS levels are not significant when compared to the PDMS content of condom lubricants.

The opinions or assertions contained herein are the private views of the author and are not to be construed as official or as reflecting the views of the Department of the Army or the Department of Defense.

Condoms, Siloxanes, Mass Spectrometry

Criminalistics Section - 2015

B169 2015 Update From the Scientific Working Group for the Analysis of Seized Drugs (SWGDRUG)

Sandra E. Rodriguez-Cruz, PhD, Drug Enforcement Admin, Southwest Laboratory, 2815 Scott Street, Vista, CA 92081*

After attending this presentation, attendees will be informed concerning SWGDRUG activities during 2014 and be updated on current and future projects.

This presentation will impact the forensic science community by providing the latest information pertaining to SWGDRUG activities, current projects, and resources provided to seized-drug analysts and laboratories.

SWGDRUG was formed in 1997 as a joint effort between the United States Drug Enforcement Administration Office of Forensic Sciences and the Office of National Drug Control Policy. **The mission of SWGDRUG is to recommend minimum standards for the forensic examination of seized drugs and to seek their international acceptance.**

SWGDRUG recommendations are available to the general public via the group's website (www.swgdrug.org). They include a code of professional practice for drug analysts as well as recommendations in the areas of education and training, methods of analysis, and quality assurance. Recently, the SWGDRUG core committee revised its recommendations pertaining to the use of reference materials to address laboratory needs during the verification of new reference materials.

SWGDRUG continues to provide the forensic community with its Mass Spectrometry (MS) and Infrared (IR) spectroscopy libraries, both of which continue to be regularly updated. Version 2.1 of the MS library was made available June 3, 2014, and currently contains more than 1,880 spectra obtained under electron ionization conditions. Included in the library are many of the recently encountered synthetic cannabinoids, substituted cathinones, and hallucinogenic phenethylamines. Version 1.1 of the IR library was made available May 30, 2014. This library contains more than 150 compounds obtained under attenuated total reflectance conditions. Both of these libraries are available in various instrument formats and can be downloaded from the SWGDRUG website and into laboratory instruments. Feedback from analysts and library users continues to be highly positive. The library will continue to be updated on a regular basis and contributions from the forensic community are strongly encouraged.

In an effort to continue providing the seized-drug community with a variety of tools, SWGDRUG also continues to publish drug monographs containing **detailed information and analytical data for reference materials**. During the last two years, more than 210 monographs have been added, containing data from reference materials **which have been analyzed, verified, and authenticated by the Drug Enforcement Administration Special Testing and Research Laboratory**. **These monographs, available via the SWGDRUG website, are intended to be used for the verification of acquired reference materials.**

With the goal of assessing the current controlled substance analogue issue, SWGDRUG has drafted a document containing general recommendations regarding analogues and structural class determinations. A final version of this document will be posted on the SWGDRUG website during 2014. The document emphasizes the need for understanding how analogues and structural classes are legally defined in different jurisdictions prior to analysts rendering opinions about a substance's classification.

This presentation will also discuss future group directions resulting from the establishment of the National Institute of Standards and Technology's (NIST's) Organization of Scientific Area Committees and current SWGDRUG projects, including the development of a supplemental document to assist laboratories in the estimation of the uncertainty associated with net weights obtained via extrapolation exercises.

The SWGDRUG core committee is comprised of representatives from federal, state, and local law enforcement agencies in the United States, Canada, Brazil, Great Britain, Germany, Austria, Switzerland, Australia, and Singapore. The following forensic organizations are represented: the European Network of Forensic Science Institutes (ENFSI), the Academia Iberoamericana de Criminalística y Estudios Forenses (AICEF), the Asian Forensic Science Network (AFSN), and the United Nations Office on Drugs and Crime (UNODC). Core committee members also include forensic science educators and representatives from forensic science organizations across the United States, the American Society of Crime Laboratory Directors (ASCLD), ASTM International, and NIST.

Controlled Substances, SWGDRUG, Drug Analysis

B170 Synthetic Drug Trends in the United States

Emily Dye, 22624 Dulles Summit Court, Dulles, VA 20147*

This goal of this presentation is to increase attendees' understanding of the synthetic drug market in the United States by illustrating the synthetic cannabinoid, substituted cathinone, and hallucinogenic phenethylamine seizure trends tracked by the Drug Enforcement Administration (DEA).

This presentation will impact the forensic science community by increasing the forensic, enforcement, and legislative communities' understanding of the current trends and flow of synthetic drugs within the United States in order to be better prepared to fight the synthetic drug epidemic.

By employing a variety of sources, information was obtained regarding drug exhibits analyzed by the eight DEA chemistry laboratories and various state and local forensic laboratories. Among the information maintained by these sources are seizure details and analytical results, which can be used to compile drug intelligence, detect the appearance of new drugs of abuse, and monitor drug trends. Data were collected for this analysis through a query of archived seizure and analysis information compiled by these sources. The information targeted in this query included the date and location of the seizure, brand names of the products seized, and substances identified during the chemical analysis. This information was compiled to construct a nationwide trend analysis of the synthetic drug market.

This study utilizes numerical data from various sources of information to track overall trends in the synthetic drug market. In addition to a breakdown of nationwide DEA synthetic drug seizure data, a number of trends will be investigated. This includes the effects of federal legislation on the number of seizures of a particular synthetic drug, as well as tracking of brand names to observe the change in active ingredients over time. Geographic trends such as location of the DEA's first encounter of a substance and prevalence of compounds over a geographic area are also explored. Trends in the use of adulterants and diluents are examined within the scope of geographical area and brand name.

Since the introduction of synthetic cannabinoids and substituted cathinones to the United States' illicit drug market in the late 2000s, the synthetic drug market has exploded. These products offer unique challenges to the entire criminal justice system, in part due to the rapid speed at which the suppliers alter these compounds to circumvent current drug legislation. The DEA Special Testing and Research Laboratory has encountered approximately 300 new psychoactive substances since they first emerged in the United States in 2009. In addition to understanding the past and present synthetic drug situation, the trend information presented may be used to predict what compounds could be popular next.

Synthetic Drugs, Trends, Designer Drugs

B171 Collection and Analysis of Fire Debris Evidence to Detect Methamphetamine, Pseudoephedrine, and Ignitable Liquids in Fire Scenes at Suspected Clandestine Laboratories

*Matthew K. Green**, Oklahoma State University-Forensic Sciences, 1111 W 17th Street, Tulsa, OK 74107; *Raymond Kuk, MS*, Forensic Science Laboratory, 6000 Ammendale Road, Beltsville, MD 20705; and *Jarrad R. Wagner, PhD*, Oklahoma State University-CHS, Dept of Forensic Science, 1111 W 17th Street, Tulsa, OK 74107

The goal of this presentation is to describe investigative tools to collect and detect methamphetamine and its precursors in fire debris evidence.

This presentation will impact the forensic science community by providing knowledge and understanding to attendees and investigators about the possibility of collection and laboratory examination of clandestine laboratory evidence at fire scenes. Implementation and application of ignitable liquid and methamphetamine detection methods will strengthen investigations and assist in determining the origin and cause of the fire.

The “One-Pot” clandestine methamphetamine production method involves the combination and use of highly reactive and flammable materials. Individuals attempting this method are creating clandestine laboratories within residences or other occupied structures and the likelihood of a subsequent fire puts anyone nearby at risk. In some jurisdictions, a fire caused by the production of methamphetamine falls under a first-degree arson statute, which can involve a much longer prison sentence when compared to an illicit drug production penalty. The ability to detect methamphetamine and the “One-Pot” precursors in the fire debris samples would strengthen the fire investigation. Although a positive detection does not guarantee methamphetamine production, the combination of the presence of an ignitable liquid and drug detection, within the totality of circumstances, has the ability to indicate the presence of a clandestine laboratory. The research was designed to answer the following questions: (1) can evidence collected at a suspected methamphetamine laboratory fire be analyzed for ignitable liquids and for the presence of methamphetamine and its precursor, pseudoephedrine; (2) would more severely charred or burned samples show a decrease in sensitivity in the analytical detection process for methamphetamine and/or pseudoephedrine; (3) are certain sample types (carpet, wood, wipes, etc.) more likely to contain the drugs of interest; and, (4) if the method for methamphetamine and/or pseudoephedrine works with advanced technologies like Liquid Chromatography with Tandem Mass Spectrometry (LC/MS/MS), is there a way for it to work with existing resources in most laboratories, such as Gas Chromatography/Mass Spectrometry (GC/MS)?

To test these questions, “One-Pot” methamphetamine reactions were carried out in a safe environment and the liquid and solid products were separated. The solid waste (sludge) and solvents were then transported to a fire research facility and the “One-Pot” methamphetamine products were used to recreate a series of fires. Small burn cells were constructed and used to represent a residential environment, then the simulated “One-Pot” laboratories were burned in each burn cell. Based upon the original placement of the “One-Pot” material and observations made during the burning process, several fire debris samples were collected from each cell, including wall wipe samples, plastic bottle remnants, wood, and carpet. Each sample was analyzed for ignitable liquids using passive headspace concentration with charcoal strips and GC/MS. Following ignitable liquid analysis, fire debris samples were extracted with LC/MS/MS running buffer and subjected to LC/MS/MS analysis to detect methamphetamine and pseudoephedrine in the fire debris samples. Additionally, the fire debris samples, charcoal strip extracts, and preserved charcoal strips were provided to local law enforcement laboratories. The preserved charcoal strips were extracted with methanol and the extract was analyzed for methamphetamine using GC/MS with positive results. This work demonstrates that fire debris analysis extraction methods can prove the presence of clandestine methamphetamine laboratories that result in arson fires.

Clandestine Laboratories, Ignitable Liquid, Methamphetamine

B172 TLC-SERS of Controlled Substances: Colloid Optimization and Drug Expansion

*Marisia A. Fikiet, BS**, 300 Boston Post Road, West Haven, CT 06516; *Kasey R. Cargill, 300 Boston Post Road, West Haven, CT 06516;* and *Brooke W. Kammrath, PhD, University of New Haven, Forensic Science Dept, 300 Boston Post Road, West Haven, CT 06516*

After attending this presentation, attendees will understand the emerging hyphenated Thin-Layer Chromatography with Surface-Enhanced Raman Spectroscopy (TLC-SERS) technique and how it can be used to identify drug mixtures.

This presentation will impact the forensic science community by expanding the use of TLC-SERS for the analysis of controlled substances.

The purpose of this research was to expand previous research on the identification of controlled substances using TLC-SERS. TLC-SERS is a hyphenated technique where a mixture is first separated using TLC followed by SERS of the TLC plate. A noble metal colloid is deposited on the resultant TLC spot and SERS spectra are directly collected. This combined technique has the potential to benefit the forensic science community because it requires less sample, time, and money when compared to other methods of analysis. In addition, it adheres to the standards for positive drug identification established by the Scientific Working Group for the Analysis of Seized Drugs (SWGDRUG).

The first goal of this research was to find a colloid that provided the most enhancement of the Raman signal for various controlled substances. Cocaine, methamphetamine, diazepam, and codeine as 4mg/ml solutions in methanol were used to evaluate the various colloid preparations. A number of both silver and gold colloids were tested and evaluated. Individually, the drugs were drawn up the TLC plate using a mobile phase of 9:1 chloroform:methanol. The plates were allowed to dry, then 20 μ l of the desired colloid was added. The resulting spectra were evaluated on uniformity across sampling, peak height, shelf life of colloid, ease of preparation, and cost of starting materials. The results of this investigation determined that silver colloids worked better than gold colloids. The best colloid was a preparation of a silver colloid first made by White and Hjortkjaer that has the largest SERS enhancement, has a long shelf life, is reproducible, and easy and fast to produce.¹ This silver colloid can be prepared in only a few minutes and has a reported shelf life of more than a year. The second goal of this research was to expand the number and types of controlled substances that can be identified using TLC-SERS. In addition, lower limits of detection were established for each drug. The controlled substances selected for inclusion in this part of the project were determined to be heavily used or on the rise by the 2012 United Nations Office on Drugs and Crime (UNODC) World Drug Report.² The drugs analyzed included heroin, methadone, morphine, codeine, fentanyl, buprenorphine, desomorphine diazepam, GHB, flunitrazepam, phenobarbital, temazepam, methamphetamine, amphetamine, cocaine, mephedrone, MDPV, MDMA, and ketamine. Methanol solutions of each drug, along with drug mixtures, were made and spotted on TLC plates. Following separation, 20 μ l of the optimized colloid were added to each TLC spot and SERS spectra were collected and analyzed.

TLC-SERS spectra are reproducible and interpretable, thus this research demonstrated that TLC-SERS is a successful method for the separation and identification of a wide range of drugs and drug mixtures. Coupling TLC with SERS is a convenient way to reduce the amount of material, equipment, and time needed for controlled substance analysis when compared to current methods and conforms to the standards set forth by SWGDRUG. This is a potentially valuable on-site technique since TLC is a relatively quick and easy technique and the Raman technology has recently become portable. The added sensitivity of the SERS allows for the possibility of very small sample size.

Controlled Substances, TLC-SERS, Colloids

B173 Detection of Drugs in Pharmaceutical Preparations Where Diversion Can Occur by Direct Analysis in Real-Time AccuTOF™-Mass Spectrometry (DART®-MS)

Amanda J. Mohs, BA, VCU Department of Forensic Science, PO Box 84307, Richmond, VA 23284; Justin L. Poklis, BS, Virginia Commonwealth University, Dept of Pharmacology & Toxicology, 410 N 12th Street, Rm 746, PO Box 980613, Richmond, VA 23219-0613; Carl E. Wolf II, PhD, PO Box 980165, Richmond, VA 23298-0165; Michelle R. Peace, PhD, VA Commonwealth University, 1015 Floyd Avenue, PO Box 843079, Richmond, VA 23284; and Alphonse Poklis, PhD, Virginia Commonwealth University, Dept of Pathology-Toxicology Laboratory, Box 98-165 MCVH/VCU Station, Richmond, VA 23298-0165*

The goal of this presentation is to inform the forensic community about a novel use of Direct Analysis in Real-Time AccuTOF™-Mass Spectrometry (DART®-MS) for screening of pharmaceutical preparations in cases of suspected drug diversion or where diversion may easily occur.

This presentation will impact the forensic science community by providing a technique for rapid identification of the contents of pharmaceutical preparations where drug diversion can occur.

Drug diversion in healthcare facilities is a multi-victim crime. Harm can come to patients, the healthcare worker, and the employer. Absence or dilution of an intended drug could result in patients receiving substandard care from their healthcare provider and may cause undue pain or anxiety in their treatment.

DART®-MS is a relatively new ionization technique that is being used to analyze a wide variety of compounds and matrices. DART®-MS offers the advantages of direct sample examination without the need for a vacuum system, minimal or no sample preparation, and high sample throughput. The use of a time-of-flight mass analyzer allows for accurate mass measurements for compounds present in or on the substrate.

A DART®-MS library was created using 20 common parental pharmaceutical preparations. These included typical surgical analgesic and anesthetic mixtures of controlled substances. Two hundred randomly selected pharmaceutical preparations were obtained from the Forensic Industrial Environmental Research and Metabolism (FIRM) Laboratory at Medical College of Virginia Hospitals at Virginia Commonwealth University. Specimens for this study were pharmaceutical preparations from “show cause testing” and routine analyses for possible diversion. These pharmaceutical preparations were screened using a DART® ion source coupled to a JEOL JMS T100LC AccuTOF™ MS operating in positive-ion mode with the following parameters: the ion source was helium gas, operated at a flow rate of 2.0L/min, a gas heater temperature of 300°C, a discharge electrode needle at 4,000V, electrode 1 set at 150V, and electrode 2 set at 250V. The resolving power of the MS was 6,000FWHM. Measurements were taken with the ion guide peak voltage at 800V, reflectron voltage at 900V, orifice 2 set at 5V, ring lens at 3V, and orifice 1 temperature at 300°C. The measurements were taken using the function switching method, allowing for collection every 0.25 seconds at the orifice 1 voltages of 20V, 30V, 60V, and 90V. The measured mass range was from 40Da to 1,000Da. The DART®-MS results were compared to both the created pharmaceutical preparations library and the National Institute of Standards and Technology library. The drug or drugs detected in each specimen was then confirmed by High-Performance Liquid Chromatography (HPLC) using a previously published method.¹

The DART®-MS was determined to have the ability to screen for and identify the main active drug or drugs in these pharmaceutical preparations by using the created pharmaceutical preparations library. The DART®-MS was also able to identify many of the excipients in the preparations. The DART®-MS analysis of the 200 pharmaceutical preparations versus the HPLC analysis of the drugs found in the pharmaceutical preparations resulted in an excellent correlation.

DART®-MS, Diversion, Pharmaceutical Preparations

B174 Quantification of Controlled Substances in Simulated Samples Using Attenuated Total Reflectance-Fourier Transform Infrared Spectroscopy (ATR-FTIR) and Principal Components Regression

*Fanny Chu, BS**, Michigan State University, School of Criminal Justice, East Lansing, MI 48824; and *Ruth Waddell Smith, PhD*, Michigan State University, School of Criminal Justice, 560 Baker Hall, East Lansing, MI 48824

After attending this presentation, attendees will understand how ATR-FTIR spectroscopy can be used in conjunction with multivariate statistics to develop and evaluate models for the quantification of controlled substances in submitted samples.

This presentation will impact the forensic science community by providing a rapid and non-destructive method to quantify controlled substances in samples using ATR-FTIR and multivariate statistical procedures.

ATR-FTIR is widely used for the analysis of submitted samples suspected to contain controlled substances. The ATR sampling accessory minimizes sample preparation and is relatively non-destructive, while FTIR is a Scientific Working Group for the Analysis of Seized Drugs Category A technique, enabling definitive identification of controlled substances in submitted samples.

In this research, Principal Components Regression (PCR) was investigated as an additional tool to aid in identification and quantification of controlled substances in sample mixtures analyzed by ATR-FTIR. PCR is a multivariate statistical procedure that combines Principal Components Analysis (PCA) and multiple linear regression. The former is used to calculate scores for the samples that are then used in the latter to generate a calibration curve that can be used for quantification purposes.

To test the utility of PCR for this application, two-component sample mixtures containing either amphetamine or methamphetamine as the controlled substance and caffeine as a cutting agent were prepared, containing 20%-100% (w/w) controlled substance, in 20% increments. These mixtures were used as the training set for the PCR model. A second set of mixtures was prepared, again using amphetamine and methamphetamine as the controlled substance and caffeine as the cutting agent. Mixtures in this set ranged from 10%-90% (w/w) controlled substance, in 10% increments. This set was used as the test set to evaluate the PCR model. All sample mixtures were then analyzed in triplicate by ATR-FTIR.

Prior to statistical analysis, data pretreatment procedures are often necessary to ensure that variation observed among the samples is chemically relevant. Examples of pretreatment procedures for spectral data include baseline correction, smoothing, scatter correction, and normalization, all of which were investigated in this research. The pretreated data were subjected to PCA and the effect of the pretreatment was evaluated based on the change in the association of replicates in the PCA scores plot compared to the untreated data. For this data set, the greatest improvement in the association of replicates was observed after applying a log transformation, followed by the baseline correction and smoothing functions available in the instrument software, and finally, standard normal variate normalization.

To develop the model, PCA was first performed on the pretreated training set data to generate scores and loadings matrices. The number of Principal Components (PCs) to include in the model was investigated using leave-one-out cross validation. The optimal model retained seven to nine PCs, with validation errors ranging from 2%-5%, indicating acceptable model performance. Multiple linear regression was then performed using the scores and PCs, in conjunction with the percent concentration of controlled substance, to generate a calibration curve. The resulting calibration curve had a correlation coefficient (r) of 0.98, indicating strong correlation between the predicted and actual concentrations of each controlled substance in the training set.

The performance of the optimized PCR model was evaluated based on the error in the predicted concentrations for the sample mixtures in the test set. Prediction errors ranged between 4% and 7%, which demonstrated the potential of PCR for quantification using spectral data. Thus, the ability to quantify controlled substances by applying PCR to spectral data collected using ATR-FTIR provides additional discriminating information about the samples.

ATR-FTIR, Controlled Substances, Multiple Linear Regression

B175 Solid State Nuclear Magnetic Resonance (NMR) of Street Drugs — The New Presumptive Drug Test

Alexander Valente, BS, Penn State University, 434 Davey Laboratory, University Park, PA 16802; Frank Dorman, PhD, 107 Whitmore Labs, University Park, PA 16802; and John Frost, PhD, ThermoFisher Scientific, 5445 Conestoga Court, Boulder, CO 80301; and Roscoe Bennett, 4310 Iroquois Avenue, Erie, PA 17110*

After attending this presentation, attendees will understand the effectiveness of NMR analysis in relationship to preemptively identifying unknown street drugs.

This presentation will impact the forensic science community by offering a new method of preemptively determining the identity of an unknown compound.

Solid state NMR has proven itself to be an interesting new tool for obtaining quick, easy, and inexpensive NMR spectra for research and instructional purposes. It can also be used to attain spectral profiles on pure samples of drugs that produce “legal highs.” This work attempts to create an NMR database of synthetic compounds known to be in use recreationally or analogs thereof. Such a library would be useful to those working in crime laboratories to identify unknown chemical compounds found at crime scenes. This test is more accurate than a color indicator and is easier to administer than a traditional mass spectrometric analysis. A single test requires only 20 minutes and is very cost effective.

Major classes of compounds tested include psychedelics, cathinones, and cannabinoids. Standard samples were provided by Cayman Chemical and street samples were provided by the Pennsylvania State Police. These street samples were mostly mixtures of compounds, most notably XLR-11, PB-22, and AB-Fubinaca. Compounds were dissolved in the appropriate deuterated solvent and centrifuged to insure the compounds completely dissolved. Any sample that crashes out of solution during injection could prove dangerous to the inner line of the instrument. The line was purged before and after each test with the corresponding solvent, then the instrument was shimmed with deionized water.

The standards’ spectra are comparable to those of the samples. An interactive library will be compiled so a drug profile can be quickly compared against a library and a presumptive identity can be established. This method will not be meant to definitively identify an unknown compound but it can aid in rapid presumptive analysis so that follow-up analyses are more targeted.

Since NMR measures excitation in proton nuclei and not fragmentation patterns, a consistent result of a given compound is not always guaranteed; however, NMR will consistently give a general profile of a given compound. If there is no discrepancy in shimming and solvent choice, NMR can be used to compare spectral similarities among unknown compounds. A quick and easy presumptive test for drugs, provided by the solid-state NMR, can be useful to save time on a more in-depth instrument and accurately identify at least the class of compound of a known substance.

NMR, Cathinones, Presumptive Test

B176 Elemental Analysis of Presumptive Clandestine Laboratory Evidence Using Laser-Induced Breakdown Spectroscopy (LIBS)

Annessa L. Burnett, BS, 1200 W Marshall, Apt 205, Richmond, VA 23220; Douglas DeGaetano, MS, Commonwealth of VA, Dept of Forensic Science, 700 N 5th Street, Richmond, VA 23219; and Rebecca Wagner, PhD, Virginia Department of Forensic Science, 700 N 5th Street, Richmond, VA 23219*

The goals of this presentation are to introduce the fundamentals of LIBS, define what is needed for trace element identification, and explain how it can be incorporated into the elemental analysis of clandestine laboratory evidence.

This presentation will impact the forensic science community by explaining the advantages of continuing to integrate LIBS in trace elemental analyses and explaining the potential use of the LIBS instrument in forensic cases.

Clandestine laboratories have been a rapidly growing problem throughout the United States. The ease of obtaining the ingredients to manufacture methamphetamine is a growing concern; therefore, analytical methods for the detection of these ingredients are critical. Numerous elemental analysis techniques currently exist in forensic science; however, LIBS is a rapidly expanding technique. LIBS uses a low-energy laser pulse in conjunction with lenses to generate a plasma when the laser beam interacts with the sample surface. A spectrum is generated that displays atomic and ionic spectral emission lines unique to the elements present. This spectrum is essentially a “fingerprint” of the respective elements present in the sample. The main objective of this research was to develop and optimize a method to identify elements commonly found in clandestine laboratory evidence. This was accomplished by examining the changes in the data caused by varying parameters of the instrument including: spot size, number of shots, spectrometer delay, repetition rate, laser intensity, accumulation of data, and gas flow. Helium and argon were used to optimize elemental excitation. The elements included in this study are commonly encountered in the methamphetamine manufacturing process including: sodium, sulfur, chlorine, red phosphorus, iodine, and lithium. An advantage of LIBS is that it can detect lighter elements, such as lithium, which is not possible with scanning electron microscopy-energy dispersive spectrometry.

The samples were evaluated during method development and optimized for each instrumental parameter. The data were reviewed for peak shape, peak abundance, and the presence of atomic and ionic spectral lines. Sample preparation techniques were also compared for each sample including: embedding in nail polish, using double-sided adhesive tape, and the use of adhesive dots. Three replicates for each sample preparation technique were examined in triplicate to observe homogeneity of the sample preparation technique as well as matrix effects. Once the optimal sample preparation technique was established, a large number of samples for each element were analyzed in triplicate to evaluate reproducibility and determine a potential threshold for elemental identification. The optimized methods for each element as well as identification threshold levels were also applied to mock case samples.

The neat samples were successfully optimized for each instrumental parameter. The intensity of the spectral lines for sodium, red phosphorus, and lithium were detected in an ambient atmosphere, while helium was needed to increase the spectral line intensities for sulfur, chlorine, and iodine samples. Some of the elements of interest displayed spectral line overlaps, and in some cases, the adhesive/sample preparation technique demonstrated interferences. A minimum of three to four spectral lines were used to determine if an element was present. Overall, LIBS has the potential to be a powerful technique for forensic trace elemental analysis.

LIBS, Methamphetamine, Clandestine Laboratories

Criminalistics Section - 2015

B177 You Got DNA From What?

Karolyn L. Tontarski, MS, DC Department of Forensic Sciences, Forensic Science Laboratory, 401 E Street, SW, Rm 3101, Washington, DC 20024*

After attending this presentation, attendees will be informed regarding interesting and challenging samples from which their peers were able to obtain interpretable DNA profiles.

This presentation will impact the forensic science community by demonstrating that their forensic biology peers have great senses of humor.

The second annual You Got DNA From WHAT? session will once again allow attendees to gather and pay homage to how amazing DNA is and to reflect on the fact that DNA has been extracted from SO many novel — and interesting — items. As testing sensitivities improve and technologies continue to change, one constant is the need for intuitive analysts to properly sample items of evidence. This session gives those intuitive DNA dudes and dudettes an opportunity to present brief PowerPoint® slide-based synopses on unique and challenging evidence samples. This event will allow DNA analysts to: (1) boast of their DNA success; (2) discuss challenges in obtaining results from a particular item of evidence; (3) ponder how they might improve on their method in the unlikely event they ever encounter this type of evidence again in their lifetime; (4) gloat vis-à-vis their analytical superiority; and, (5) figure out how to one-up last year's presenters!

This 2nd annual Friday evening You Got DNA From WHAT? session, the brainchild of Criminalistics Section Fellow Daniel Petersen, is intended to be informal, entertaining, and informational (in that order!). The list of You Got DNA From WHAT? speakers, as well as the subject matter of each presentation, will be kept under wraps until the last minute to keep attendees wondering.

If you've ever found yourself at loose ends on the Friday night prior to the meeting wrapping up on Saturday and you've ever made this exclamation, or wish you had, this session is for you!

DNA, Unique Samples, Sensitivity

B178 Improving Methods for the Recovery and Analysis of Touch DNA From Fingerprints at Crime Scenes

*Jennifer E. Templeton, MSc**, School of Biological Sciences, Flinders University, Bedford Park, Adelaide, South Australia 5063, AUSTRALIA; and *Adrian Linacre, PhD*, School of Biological Sciences, Flinders University, GPO 2100 Bedford Park, Adelaide 5001, AUSTRALIA

After attending this presentation, attendees will better understand the most effective method of recovering DNA from touched or handled items at crime scenes for the purpose of human identification. The presentation will guide the audience through the optimum swabbing technique, the best swabbing media, and describe the process of direct Polymerase Chain Reaction (PCR) with the extraction step omitted.

This presentation will impact the forensic science community by highlighting the benefits of direct PCR in a forensic context and making the audience aware that an extraction step is not always beneficial for processing touch DNA swabs. This method reduces time and labor costs and minimizes the risk of contamination while increasing the likelihood of obtaining a meaningful profile for interpretation. The methodology described can easily be adapted into mainstream forensic practice.

The ability to generate a DNA profile from a fingerprint for the purpose of human identification will have significant implications for solving a broad spectrum of criminal investigations, ranging from theft to crimes of violence. DNA retrieved from fingermarks deposited by touch (referred to as “touch” DNA) is often degraded, limited in quantity, and may comprise elements that co-extract with the DNA and hinder subsequent amplification. There is a limit of sensitivity that still precludes many items touched at a scene from generating a useable DNA profile, despite their potential importance in a criminal investigation. Examples of these sample types include triggers, steering wheels, bullet cartridges, and handles of knives. In many criminal cases, the ability to retrieve the maximum amount of DNA from “touch” DNA samples is of paramount importance and crucial to resolving the case.

The first DNA profile generated from a fingerprint was reported over a decade ago and revolutionized forensic science. In spite of this, recent research demonstrates an extremely low success rate (5%-6%) using standard methodology in terms of generating a profile from “touch” DNA sources that is deemed suitable for identification purposes. This highlights the need for improved methodology. A novel method that routinely generates meaningful DNA profiles from latent fingermarks for the purpose of human identification is reported here. Depending on the type of short tandem repeat DNA profiling kit used, the success rate is 62% to 70% and is not dependent on an enhanced PCR cycle number. Its novelty that will be discussed involves an optimized swabbing technique and detergent media, omission of a DNA extraction process, and the addition of PCR facilitators to the reaction vessel. By using a direct PCR approach, full DNA profiles from fingerprints that have been deposited only 15 minutes after a person has washed his/her hands can routinely be generated.

A total of 34 people washed their hands to remove external DNA and after only 15 minutes deposited fingermarks from all digits of their dominant hand onto a plastic substrate. Nylon fibers pre-moistened with heated detergent were used to collect any DNA from the substrate and then placed directly into the amplification reaction tube. From the 170 fingermarks tested, only four DNA profiles (<1%) failed to yield DNA and 116 DNA profiles (68%) were recorded with sufficient data to be used in DNA databases. This finding demonstrates a 62-fold difference between standard methodology and the improved DNA-capture method.

The method has since been applied to casework to generate a DNA profile from a single fingermark deposited on a drug wrap, illustrating the potential for significant impact on forensic practice and criminal investigations. The process described is simple, elegant, and should readily gain general acceptance into legal systems. This will allow meaningful DNA profiles to be generated routinely from touched items where current forensic practice has little or no chance of generating a DNA profile.

DNA Profiling, Touch DNA, Direct PCR

Criminalistics Section - 2015

B179 Assessment of Fingerprints for Forensic Short Tandem Repeat (STR) Analysis

Lana Ostojic, MS, OCME of NYC, 421 E 26th Street, New York, NY 10016*

After attending this presentation, attendees will understand the challenges of working with fingerprints. The presentation will focus on the evaluation of cellular and DNA content of a single fingerprint and the ability to produce Combined DNA Index System (CODIS)-eligible STR profiles.

This presentation will impact the forensic science community by providing information on investigative values of fingerprints as forensic DNA samples.

Touched or grabbed items, such as handles of weapons, tools, or other objects with no apparent biological staining, can be used as evidence in investigations in a wide variety of criminal cases, including homicides, sexual assault, and property crimes; however, there are some fundamental difficulties when working with samples collected from touched objects, including variability in quantity and quality of extracted DNA. Fingerprints can result in little-to-no DNA but also in DNA profiles that are suitable for upload to forensic STR databases. Importantly, sometimes fingerprints are the only available source for forensic DNA testing. Obtaining high-quality DNA profiles that can be used for CODIS from the aforementioned types of evidences has a tremendous potential in the investigation of a wide variety of criminal offenses.

In a longitudinal study, the New York City Office of Chief Medical Examiner Department of Forensic Biology collected more than 700 fingerprints. Unrelated volunteers provided several series of fingerprints on separate days. Sample collection was performed under similar conditions to minimize variations. Following deposition, the fingerprints were assigned a quality score of one to five (sparse to dense shedding), aided by the use of an Olympus® SZX-16® stereomicroscope. Individuals differed in their shedding scores; however, most fingerprints scored three or four. A Chi-square test on the data confirmed that it is not possible to classify people as good or bad shedders. Nevertheless, some individual's scores tended to be slightly lower, enabling these persons to be described as "bad shedders" relative to individuals who's scores tended to be a little higher. A Chi-square test also revealed no differences between left and right hand regarding the shedding score, indicating that shedding is independent of hand dominance or how frequently one hand is used over the other.

The laboratory further investigated whether there is a correlation between shedding score and the amount of DNA recovered. Linear regression showed that one unit in shedding score is associated with a 2.24pg/μl increase in the amount of DNA recovered; however, this is not significant ($p=0.20$) indicating shedding score is not helpful in predicting DNA amount. The laboratory also investigated the correlation between shedding score and completeness of the DNA profile obtained. Linear regression showed that each unit of shedding score was associated with a 4.2% increase in the percent profile obtained and this was significant ($p=4.8 \times 10^{-4}$); however, because of the great variability in profile quality, shedding score alone was not a reliable predictor of profile quality. A possible explanation for this could be that many deposited cells in a fingerprint may not be nucleated, plus cell flakes may or may not be carriers for extracellular DNA which is not visible microscopically.

Most of the STR profiles obtained from the fingerprints were partial. Profiles that were at least 70% complete were considered as valuable, since such profiles could be used to search databases. The probability to obtain such profiles from a single fingerprint varied, but was approximately 50%. In conclusion, a fingerprint can be considered as a potential source of DNA for forensic identification.

Fingerprints, STR Profiles, Touched Items

B180 Obtaining STR-Quality Touch DNA From Archived Latent Fingerprints

Aryn M. McClain, BS, Virginia Commonwealth University, 1015 Floyd Avenue, PO Box 843079, Richmond, VA 23284; Marilyn T. Miller, EdD, VA Commonwealth University, 1015 Floyd Street, Rm 3000A, Box 843079, Richmond, VA 23284-3079; and Tracey Dawson Cruz, PhD, Virginia Commonwealth University, 1015 Floyd Avenue, PO Box 843079, Richmond, VA 23284*

After attending this presentation, attendees will understand the importance of collecting and extracting touch DNA evidence from each contact surface for both freshly collected and archived fingerprints.

This presentation will impact the forensic science community by helping attendees to better understand the fragility of such evidence and recognize the need to develop a successful protocol for extracting and typing the highest-quality DNA possible from these types of DNA sources.

Customary collection methods for latent fingerprints discovered at crime scenes involve powder dusting and tape-lifting the prints, followed by attaching the fingerprint-containing adhesive to paper backing cards for storage, thus forming an archived latent fingerprint. Ultimately, this approach allows the crime scene investigator to preserve the latent print(s) but also sandwiches valuable touch DNA evidence between the adhesive and paper surfaces; however, it is uncommon for forensic laboratories to extract DNA that has been stored in this manner due to low success rates and minimal research on DNA extraction methods for archived fingerprints. Further, it is uncommon for investigators to physically collect fingerprints deposited on paper surfaces after on-scene enhancement and photography, leaving valuable trace DNA behind.

In this study, the goal was to determine if it would be possible to obtain sufficient high-quality DNA for successful Short Tandem Repeat (STR) amplification from archived fingerprints. Eight sets of fingerprints were collected from both glass and paper surfaces from five volunteers. From these, multiple variables were tested and compared, including freshly collected samples versus aged samples, glass deposition versus paper, black magnetic enhancement versus standard black dusting powder, and recovery of DNA from the adhesive surface of the archived sample versus the paper side. Two different silica-based solid phase column DNA extraction methods were tested. Following extraction, all samples were quantified using a real-time Polymerase Chain Reaction (PCR) -based human-specific assay and STR loci were amplified and analyzed using standard methods. As expected, “fresh” fingerprint samples yielded higher DNA concentrations ($0.175\text{ng}\pm 0.3\text{ng}$) than “aged” fingerprint samples ($0.126\text{ng}\pm 0.3\text{ng}$). Enhancement powder used did not affect DNA yield, as samples visually enhanced with black magnetic dactyloscopic powder yielded approximately the same DNA yield ($0.166\text{ng}\pm 0.3\text{ng}$) as samples enhanced with standard black dusting dactyloscopic powder ($0.136\text{ng}\pm 0.3\text{ng}$). Furthermore, STR-quality DNA was obtainable from both the adhesive sides (avg. $0.356\text{ng}\pm 0.38\text{ng}$) and paper sides (avg. $0.211\text{ng}\pm 0.27\text{ng}$) of archived fingerprints. This data demonstrates two important findings. First, quantifiable touch DNA is obtainable from latent prints left on paper surfaces, and, thus, latent fingerprints deposited on paper should be collected from crime scenes for potential DNA analysis after on-scene enhancement and photography. Second, both the adhesive and paper surfaces of an archived fingerprint card should be processed for DNA analysis rather than processing only the adhesive side, the latter of which is standard protocol for labs attempting analysis of this sample type.

Three DNA collection methods were also evaluated: direct cuttings, double-swab technique with lysis buffer as the diluent, and single-swab technique with ultrapure water as the diluent. Of these methods, the double-swab technique yielded three times more DNA ($0.497\text{ng}\pm 0.45\text{ng}$) than the other two collection methods. Interestingly, none of the samples showed signs of PCR inhibition, regardless of chemical treatment for fingerprint enhancement; however, only samples collected using the single-swab technique ($n=5$) yielded STR profiles. Of these samples, 60% yielded near-complete profiles; however, all samples showed electropherogram data indicative of DNA degradation.

The results of this study show that it may be possible to obtain STR-quality DNA from archived, paper-backed latent fingerprints. While these results are encouraging, it is well known that outdated methods for collecting latent prints often did not include the use of gloves or other personal protective equipment and that fingerprint brushes are/were often used for multiple collections without cleaning. Thus, future studies will include thorough contamination and source attribution studies as well as an evaluation of the effects of brush reuse for collection of latent fingerprints.

Touch DNA, DNA Extraction, Archived Fingerprints

B181 Non-Destructive Biological Evidence Detection and Collection Using the ESDA®-Lite

Dane T. Plaza*, 10430 Furnace Road, Ste 107, Lorton, VA 22079; Jamia J. Mealy, MS, Bode Technology, 10430 Furnace Road, Ste 107, Lorton, VA 22079; Jack N. Lane, BS, Bode Technology, 10430 Furnace Road, Ste 107, Lorton, VA 22079; Michael N. Parsons, MS, 10430 Furnace Road, Ste 107, Lorton, VA 22079; Abigail S. Bathrick, MFS, 10430 Furnace Drive, Lorton, VA 22079; and Donia Slack, 10430 Furnace Road, Ste 107, Lorton, VA 22079

After attending this presentation, attendees will understand the basic operating principles of collecting human DNA evidence using the Electrostatic Detection Apparatus (ESDA®)-lite. Additionally, attendees will learn of the potential forensic applications of utilizing alternative collection methodologies such as dry-swabbing and the ESDA technique for non-destructive biological evidence detection and collection from paper substrates.

This presentation will impact the forensic science community by providing a confident approach to non-destructive biological evidence sampling from paper substrates. This technique would allow forensic DNA analysts to detect and collect biological materials from an evidentiary item without damaging its structural integrity and/or interfering with any subsequent examinations. Non-destructive collection of biological samples for DNA processing would preserve the physical integrity of evidentiary items to allow for more thorough evaluations by other forensic disciplines subsequent to DNA processing. The additional information gained from items processed in this manner could aid in the conviction or exoneration of individuals associated with evidentiary items containing touch DNA, such as questioned documents, entry-point surfaces, clothing, and other handled items. Evidence processed in a non-destructive manner would also remain available for future evaluations that could prove pivotal to the outcome of a cold case investigation and/or criminal retrial. All of the tools and techniques suggested are either relatively inexpensive or are already available in crime laboratories and could easily be incorporated into standard laboratory operating procedures.

The ESDA®-lite was systemically evaluated for its ability to non-destructively collect DNA from latent fingerprints deposited on various paper substrates for Short Tandem Repeat (STR) DNA profiling. Fingerprints were deposited on a variety of paper substrates that included resume paper, cotton paper, magazine paper, currency, copy paper, and newspaper. A total of 162 samples were prepared. For each collection technique, 54 latent fingerprints were sampled. Three DNA collection techniques were performed: ESDA collection, dry swabbing, and substrate cutting. Efficacy of each collection technique was evaluated by the quantity of DNA present in each sample and the percent profile generated. For each collection technique and substrate type, the DNA quantities were averaged across all three donors (Table 1). Large standard deviations were observed due to the wide range of DNA quantities deposited by the different fingerprint donors. Across all substrates, full and high partial profiles were generated for 65% of the samples collected with the ESDA technique, 93% of the samples collected via dry swabbing, and 52% of the samples collected with a destructive collection technique. Profiles in which 70% of the alleles (22 of 32 alleles or 11 loci) were obtained were considered to be high partial profiles.

Table 1: DNA quantity (ng) present in fingerprint samples collected via the ESDA, dry swabbing, and destructive (cutting) collection techniques.

Paper Substrate	Mean DNA Quantity (ng)		
	ESDA	Dry Swabbing	Destructive
Resume	0.367 ± 0.601	0.521 ± 0.348	0.061 ± 0.097
Cotton	0.217 ± 0.264	0.547 ± 0.519	0.000 ± 0.000
Magazine	0.332 ± 0.308	1.049 ± 1.186	0.130 ± 0.149
Currency	0.320 ± 0.696	0.623 ± 0.319	0.187 ± 0.184
Copy	0.170 ± 0.185	0.798 ± 0.460	0.550 ± 0.881
Newspaper	0.170 ± 0.226	0.267 ± 0.245	0.677 ± 0.453

Both the ESDA and dry swabbing non-destructive sampling techniques outperformed the destructive methodology of substrate cutting. A greater number of full profiles were generated from samples collected with the non-destructive dry swabbing collection technique than were generated from samples collected with the ESDA; however, the ESDA also allowed the user to visualize the area of interest while non-destructively collecting the biological material. The ability to visualize the biological material made sampling straightforward and eliminated the need for numerous, random swabbings/cuttings. Based on these results, the non-destructive ESDA collection technique has great potential for real-world forensic implementation.

B182 Examination of Rapidly Mutating Y-STR Loci for Increased Resolution of Common Haplotypes Using a Large Multiplex Kit

Michael D. Coble, PhD, 100 Bureau Drive, MS 8312, Gaithersburg, MD 20899-8312; Katherine B. Gettings, PhD, NIST, 100 Bureau Drive, Mail Stop 8314, Gaithersburg, MD 20899; and Peter M. Vallone, PhD, 100 Bureau Drive, Gaithersburg, MD 20899-8311*

The goal of this presentation is to introduce attendees to a set of rapidly mutating Y-chromosomal Short Tandem Repeat (Y-STR) markers in a commercially available multiplex kit. Population statistics on the specific loci examined and their utility for discriminating closely related males will be presented.

This presentation will impact the forensic science community by introducing the usefulness of a set of rapidly mutating Y-STR loci in a commercially available kit to increase discrimination among closely related males.

Y-STR testing has become an important tool for forensic investigations, especially in DNA mixture samples where low-level male DNA is mixed in a high female DNA background. Until 2014, only two commercial kits of 17 and 23 Y-STR markers were available for the forensic community that provide relatively high discrimination among unrelated individuals, with a discrimination capacity greater than 97% (National Institute of Standards and Technology (NIST), unpublished data).^{1,2} Given the haploid nature of the Y-chromosome, a match between the evidence and the accused is evaluated in terms of how frequently the haplotype is observed in a relevant database. In addition to the limitation of Y-STR statistical results restricted to the size of the database, the current set of Y-STR markers are limited at separating related males such as fathers, sons, and brothers.

Recently published Rapidly Mutating (RM) Y-STR loci with mutation rates from roughly 1% to 7% per meioses were evaluated at NIST.^{3,4} To assess the utility of RM Y-STR markers for casework, NIST has evaluated the Yfiler® Plus kit released for commercial use in 2014. The Yfiler® Plus kit includes seven rapidly mutating markers intended to increase discrimination among closely related individuals. The evaluation used a set of unrelated population samples to determine population genetics parameters, such as haplotype diversity, and a set of father-son samples to determine the usefulness of the markers for distinguishing related males.

NIST population samples of more than 600 unrelated individuals in three United States groups, Caucasian, African American, and Hispanic, were initially tested with the Yfiler® Plus kit.⁵ Subsequently, nearly 400 father-son samples among United States Caucasians, African Americans, Asians, and Hispanics were also tested.⁶ All samples had been previously typed using the original two commercially available forensic Y-STR kits.^{1,2}

As a result of the testing, NIST found that the RM Y-STR markers provided increased discrimination and variation among common haplotypes unresolved using the original commercially available Y-STR kits. Additional Y-STR loci, especially from rapidly mutating markers, can be useful for increased discrimination among closely related males; however, caution should be considered in the interpretation of these markers when discrepancies occur among close relatives that could lead to incorrect exclusions based upon a pre-determined number of mismatches (e.g., in missing person cases).

B183 Inferring Bloodstain Age With a Mobile Spectrometer for Forensic Crime Scene Investigation

Nichole Sutton, BS, 2014 Horizon Court, Apt 204, Woodbridge, VA 22025; Michael Harradon, BS, Massachusetts Institute of Technology, 233 Massachusetts Avenue, Cambridge, MA 02139; Paul C. D'Angio, PhD, Booz Allen Hamilton, 3811 N Fairfax Drive, Ste 600, Arlington, VA 22203; Michelle R. Mendonca, MFS, 825 New Hampshire Avenue, NW, Apt 413, Washington, DC 20037; Kristen L. O'Connor, PhD, Booz Allen Hamilton, 3811 N Fairfax Drive, Ste 600, Arlington, VA 22203; Zigurts K. Majumdar, PhD, Booz Allen Hamilton, 3811 N Fairfax Drive, Ste 600, Arlington, VA 22203; and Daniele S. Podini, PhD*, Department of Forensic Science, 2100 Foxhall Road, NW, Washington, DC 20007*

After attending this presentation, attendees will better understand the evaluation of aging bloodstains using optical spectrometry to develop an application for a smartphone-like device capable of predicting the age of a bloodstain based on a picture captured with a camera phone. Data obtained from an Ocean Optics® spectrometer was compared to data obtained with a portable mobile spectrometer to determine the mobile device's ability to quantify bloodstain age.

This presentation will impact the forensic science community by providing preliminary data for the development of a tool for crime scene investigators who need field-ready, hand-held forensic solutions to allow them to process, prescreen, triage, and analyze forensic evidence in the field.

The application is based on the principle of reflective spectroscopy. Spectral reflectance of a bloodstain changes over time, as the blood itself undergoes changes in its chemical composition while exposed to the environment. By analyzing how the spectroscopy data changes as blood ages, the data may be characterized in order to create a smartphone application. The smartphone application would be used together with a modular attachment used to record the spectral reflectance and analyze the data to predict the age of the bloodstain. Spectroscopic measurements of bloodstains of varying ages from zero hours to 1,400 hours were taken with two different devices: (1) a commercially available, laboratory-grade spectrometer (Ocean Optics®) using its respective analysis software; and, (2) a smartphone with an attached module that uses the camera to acquire a dispersed optical spectrum. The devices were set up adjacent to one another and measurements of one sample at a time were taken by each device. Samples consisted of bloodstains, approximately 2.5 centimeters in diameter. The samples were collected from a single individual via a lancet prick on a finger (Institutional Review Board-approved procedure). Once the finger was pricked, it was touched directly to a square of white cotton cloth until the 2.5 centimeter diameter was obtained. The samples were then placed, ten at a time, on a rotating platform that moved under the two collecting devices. The platform, accompanied with a Light-Emitting Diode (LED) light source, operated on a timer so that spectra data could be collected on each sample at specific time intervals. A blank white cloth was included to normalize the reflectance data. The platform rotated one sample at a time, paused for 30 seconds at the new location, a measurement was taken by both devices, and rotated once again. At 25 seconds into the pause, the LED light turned on, each device took a measurement, and the light turned off before the platform rotated again. This was done for two complete rotations of each sample set. This allowed each of the ten samples to be measured every five minutes.

Analysis of the data has resulted in the development of a method that allows for the prediction of the age of a bloodstain based on the spectroscopic measurements with an inference error that increases with the age of the stain. Based on prior studies and on data generated in this project, an algorithm was developed that can process data in real-time on a smartphone. Results suggest that the processing algorithms are promising for use in crime scene analysis to distinguish samples of differing age. Preliminary results are based on 318 spectra, for which confidence intervals at 95% or greater were calculated, based on the t-distribution, to determine if samples of varying age could be reliably distinguished when assuming a constant temperature and humidity over the measurement conditions. The following statements can be made with a 95% confidence interval from current data: a bloodstain <1.5 hours old can be identified as younger than a >5.0-hour-old stain; a <5.0-hour-old stain can be identified as younger than a >24-hour-old stain; a stain <24 hours old can be identified as younger than a stain >20 days old. The algorithms are being refined to increase accuracy and to provide greater robustness against variations in temperature and humidity. Accuracy in predicting the absolute age of the bloodstain will be discussed using more data points. Further analysis and development will enable the production of a field-ready smartphone application that can quickly help prioritize sample collection and processing, resulting in increased efficiency at the crime scene.

B184 Increasing Discrimination of Degraded DNA Using Quantifiler® Trio With the Ion Personal Genome Machine® Sequencer

Joseph P. Chang, BS, Thermo Fisher Scientific, 180 Oyster Point Boulevard, South San Francisco, CA 94080; Allison Holt, PhD, 180 Oyster Point Boulevard, South San Francisco, CA 94080; Narasimhan Rajagopalan, MS, Thermo Fisher Scientific, 180 Oyster Point Boulevard, South San Francisco, CA 94080; Robert Lagace, BS, 850 Lincoln Centre Drive, Mail Stop 404-1, Foster City, CA 94404; Sharon Wootton, PhD, 850 Lincoln Centre Drive, Foster City, CA 94404; Sheri Olson, MS, Thermo Fisher Scientific, 180 Oyster Point Boulevard, South San Francisco, CA 94080; Nnamdi Ihuegbu, PhD, 180 Oyster Point Boulevard, Rm 258, South San Francisco, CA 94080; Reina Langit, MS, 850 Lincoln Centre Drive, Foster City, CA 94404; and Chien-Wei Chang, PhD, 850 Lincoln Centre Drive, MS 404-1, Foster City, CA 94404*

After attending this presentation, attendees will learn how Single Nucleotide Polymorphisms (SNPs) and Next Generation Sequencing (NGS) technologies can improve the analysis and identification of degraded DNA samples.

This presentation will impact the forensic science community by presenting a possible complementary solution on the use of NGS in degraded DNA casework analysis. Attendees will observe that the Probability of Identity (PI) values provided by partial STR profiles will be further augmented by PI values from SNPs.

Forensic casework analysis that involves degraded or compromised DNA samples in trace amounts often shows allele dropout at larger molecular weight loci, which results in partial profiles that may have limited or no probative value. It is beneficial to have accurate DNA quantification data to enable forensic analysts to critically evaluate how to select the appropriate downstream STR technologies in order to obtain the most probative results with challenging casework samples. At the threshold that STR kits cannot provide complete profiles anymore, forensically informative SNPs can provide the additional discriminatory power to complement partial or no STR profiles produced by Capillary Electrophoresis (CE). The HID-Ion AmpliSeq™ Panels were developed to provide an alternative and complementary approach to current human identification STR technologies, as well as utilize NGS high-multiplexing capabilities.

The HID-Ion AmpliSeq™ Identity Panel consists of 90 autosomal, of which 85 are unlinked, and 34 upper Y-clade markers. These Identity Informative SNPs (IISNPs) were selected due to their high heterozygosity and low population heterogeneity. Using an input of pristine DNA, the combined 85 unlinked IISNPs provide a random match probability of 10^{-33} in most parts of the world. The 34 upper Y-Clades were selected from the Y-Phylogenetic Tree.¹

The HID-Ion AmpliSeq™ Ancestry Panel consists of 55 Kidd and 123 Seldin markers.^{2,3} These Ancestry Informative SNPs (AISNPs) were selected to infer ancestry from the major eight global regions. These AISNPs are highly supported by Kidd's ALFRED database, which contains a considerable amount of allele frequency variation and population statistics.⁴

This study intends to evaluate data to determine how to proceed with sample processing for degraded DNA samples. Using a human male genomic DNA, PB001, varying degrees of degradation were produced with a combination of both mechanical and enzymatic shearing techniques. Then, utilizing the Quantifiler® Trio DNA Quantification Kit, a Degradation Index (DI) was produced to evaluate the integrity of the degraded PB001. The DI is a ratio of the Small Autosomal (SA) target concentration to the Large Autosomal (LA) target concentration in the stock. The SA locus is 80bp in length while the LA locus is 214bp in length. For four levels of PB001 degradation — none (control), low, medium, and high — the observed DIs were 0.9, 3.4, 37.3, and undefined, respectively. The DI for the highly degraded sample was undefined because there wasn't enough LA.

A correlation was observed between DI and probative value obtained from CE STR and Ion PGM™ System SNP results. Using the GlobalFiler® kit, the PIs for Africans, Asians, Caucasians, and Hispanics for the sample whose DI was 37.3, were 7.14×10^{-3} , 1.01×10^{-2} , 9.201×10^{-3} , and 1.22×10^{-2} , respectively. For the SNP panels for the same sample, the PIs for Global, Asian, Ad-Mixed American, African, and European were 2.21×10^{-14} , 1.89×10^{-13} , 2.41×10^{-14} , 3.42×10^{-13} , and 1.35×10^{-14} , respectively. The control, low, and medially degraded samples did not lose any SNPs. A plot of PI vs. DI was prepared to illustrate the best downstream sample processing for samples identified with varying levels of degradation.

This work demonstrates that the HID-Ion SNPs offer complementary discrimination power to CE STR data for samples that would be considered “poor” quality for STR processing in a casework laboratory based upon their DI value.

Degraded DNA, Next Generation SNP Sequencing, Quantification

B185 Single-Step Photobleaching: A PCR-Free Alternative to Typing Low-Copy Number Templates

Tanya M. Simms, PhD, University of Kansas, 1251 Wescoe Hall Drive, Lawrence, KS 66045; and Matthew Antonik, 1082 Malott Hall, Dept of Physics and Astronomy, Lawrence, KS 66045*

After attending this presentation, attendees will better understand photobleaching, a single molecule technique that allows examination of the individual DNA molecules (rather than ensemble measurements) in a sample. In addition, attendees will realize that this strategy is advantageous for samples with too few molecules for Polymerase Chain Reaction (PCR) and that photobleaching experiments are not subject to the stochastic variation that is typical of PCR, particularly when Low-Copy Number (LCN) templates are amplified.

This presentation will impact the forensic science community by educating them on alternative strategies in dealing with LCN templates. Specifically, the goal is to stress that single molecule techniques, such as photobleaching, examine individual DNA molecules in a sample rather than making ensemble measurements as with PCR. In addition, the presentation emphasizes that by attaching genomic DNA to a glass surface, the same individual DNA molecule can be repeatedly measured. Finally, the forensic science community should realize that by using this technique, which is non-destructive, it should be able to recover the sample after performing these experiments, making it available for traditional PCR analysis if need be.

STR typing and next generation sequencing technologies rely upon PCR-based methods for the exponential amplification of DNA markers; however, the PCR process is known to have its limitations with regard to DNA that is degraded or is low in copy number. While the latter results in stochastic variations that are difficult for forensic investigators to interpret, the former can prevent PCR amplification altogether, particularly when targeting larger-sized fragments. Therefore, in this study, these issues are avoided by completely bypassing the PCR process. Instead, well-established single molecule-based approaches, which are sensitive enough and have the resolution (within one nm) to examine individual DNA molecules within forensically challenged samples, are utilized. The single molecule techniques also provide the added benefit of being reproducible, as long as the DNA of interest is anchored to the glass surface.

Specifically, single-step photobleaching was performed, a single molecule method that enables determination of the number of STR repeats at the TPOX locus by directly counting the number of steps in the fluorescence signal as the dye molecules are destroyed over time by exposure to light. The DNA molecules utilized for these experiments were generated by annealing primers and fluorescently labeled eight bp oligonucleotides to various single-stranded DNA templates, consisting of 6, 8, 12, and 16 tetranucleotide repeats flanked by two primer binding regions. The annealed double-stranded DNA construct was ligated using a previously published DNA ligation protocol. Upon completion, the size of each of the ligated DNA templates was confirmed by Capillary Electrophoresis (CE) on a 3700xL genetic analyzer. Following CE, the ligated products were diluted to single molecule concentration (10 to 100 picomolar) and then immobilized onto separate coverslips that were functionalized with poly-L-lysine. Each coverslip was subsequently examined by (TIRF), a popular single molecule technique that illuminates only those molecules present at the water-glass interface, and monitored until all the dyes in the region of interest had been bleached. Using this approach, this study was able to visualize two, three, five, and seven distinct steps when imaging DNA templates consisting of 6, 8, 12, and 16 tetranucleotide repeats, respectively. To confirm these results, the ligation reactions were performed again using eight bp oligonucleotides tagged with five nm gold nanoparticles and the products imaged via Transmission Electron Microscopy (TEM). As with the TIRF approach, the TEM images also revealed clusters of two, three, five, and seven beads using the abovementioned template sequences. Altogether, this data illustrates that the combined ligation/TIRF approach is a promising mechanism for determining the number of STR repeats at a particular locus; however, further work is required to be able to covalently (versus electrostatic interactions) attach the DNA to the surface of the glass. In doing so, this research will be able to examine genomic DNA, melt it, wash off the complementary strand, and repeat the experiment a number of different times for consistency. Although this process will enable generation of a genetic profile in high-profile cases where the DNA evidence is limited or compromised, the resolution will be lower than with traditional STR typing technologies. Additionally, it is hoped that by refining the attachment strategies the genomic DNA will be recoverable from the coverslip, making it available for traditional PCR analysis if so desired.

PCR-Free, Low-Copy Number, Single Molecule

B186 Development of a Novel DNA Phenotyping System Using Genome-Wide SNP Data

Ellen McRae Greytak, PhD*, Parabon NanoLabs, Inc, 11260 Roger Bacon Drive, Ste 406, Reston, VA 20190

After attending this presentation, attendees will: (1) learn the differences between traditional DNA analysis using Short Tandem Repeats (STRs) and modern DNA genotyping using Single Nucleotide Polymorphisms (SNPs); (2) understand how the genetic content of DNA encodes the observed variations in human appearance; (3) gain an appreciation for how these genetic variants can be used to predict traits (phenotypes); and, (4) learn about a new methodology for producing predictive models for forensic traits from genome-wide SNP data.

This presentation will impact the forensic science community by presenting a novel methodology for the discovery of significant SNPs for forensic traits and the development of those SNPs into predictive models that can be used for DNA phenotyping or kinship analysis.

Traditional forensic DNA analysis uses STRs to match an individual to a DNA sample by testing crime scene DNA against known suspects or a DNA database, such as the Combined DNA Index System. When this fails to yield a match, alternate approaches are required to generate leads from a DNA sample. DNA phenotyping refers to the use of SNPs, DNA variants that code for differences between individuals, to predict an individual's appearance based only on his or her DNA. Prior work on DNA phenotyping has been limited to using only a few SNPs which have been identified in the literature as being individually significant for prediction of eye and hair color and ~100 SNPs to calculate large-scale ancestry (i.e., African, European, or East Asian). Presented here are the results of work to build a novel DNA phenotyping system, developed under funding from the United States Department of Defense, that employs thousands of SNPs for the prediction of complex traits, resulting in improved prediction accuracy over a broader phenotypic range. This system can be applied to individuals from any ethnic background, even admixed individuals.

The predictive models were built using genome-wide genotype data from more than 2,500 subjects for eye color and hair color and from more than 500 subjects for skin color and freckling. Each subject's proportional ancestry in seven global populations (Africa, Middle East, Europe, Central Asia, East Asia, Oceania, and America) was calculated by comparing more than 20,000 SNPs, carefully selected from across the genome, against a set of more than 2,200 background subjects from known populations. This approach can detect even low levels of admixture. Within-continent ancestry (e.g., Northeast vs. Northwest Europe) and the principal components of ancestry were also inferred. These values were then used as covariates for the discovery of significant SNPs associated with each forensically relevant pigmentation phenotype. SNP discovery was performed using advanced data mining techniques that search not only for SNPs that individually contribute to phenotype, but also those that interact in a non-additive (epistatic) fashion. This was achieved using a custom distributed implementation of the Multifactor Dimensionality Reduction (MDR) algorithm.

Using the SNPs discovered during data mining as well as ancestry SNPs, predictive models were constructed using advanced machine-learning algorithms. These techniques allow non-linear variable combinations and are not negatively impacted by the inclusion of extraneous variables. The entire mining and modeling process was performed within a ten-fold cross-validation framework to allow all of the data to be used to build a model while still allowing for accuracy evaluation using out-of-sample predictions. A statistical procedure for evaluating confidence has been developed, which calculates a consistency value for each new prediction for each possible category (e.g., red, blond, brown, and black hair color). Each prediction is presented with a measure of confidence as well as a list of trait categories that can be excluded with very high confidence. DNA from an unknown subject can be run through these predictive models to produce a physical profile. Blind validation testing has been performed for ancestry, eye color, hair color, and skin color on 24 subjects (Table 1) from a range of ethnic backgrounds (European, African-American, Central Asian, and Middle Eastern). The final system has been successfully tested using as little as two ng of extracted DNA.

Table 1: Results of blind validation testing. For each trait, the average consistency for the absolute correct category and the frequency at which the absolute correct category was found to have the highest consistency (two very conservative estimates of accuracy) are reported.

Trait	Average Consistency for Absolute Correct Category	Frequency of Highest Consistency for Absolute Correct Category
Eye Color	76.1%	84.8%
Hair Color	67.7%	95.7%
Skin Color	56.0%	82.6%

Criminalistics Section - 2015

A method to determine the degree of relatedness between two subjects using genome-wide SNP data was also developed. This model uses hundreds of thousands of SNPs to ascertain the precise level of similarity between two individuals' genomes. This method has >90% accuracy up to third-degree relatives and can distinguish up to sixth-degree relatives from unrelated pairs with >95% accuracy. Validation results for both the DNA phenotype and kinship inference systems will be presented, along with plans for future enhancement of the underlying processes and software.

SNP, DNA Phenotyping, Kinship Inference

B187 Use of Likelihood Ratios to Unlock Information in Various Short Tandem Repeat (STR) Kits' Threshold Validation Data Sets With the Use of Lab Retriever

Megan M. Boll, MSFS, NMS Labs, 2300 Stratford Avenue, Willow Grove, PA 19090; Britton L.F. Morin, MSFS, 2300 Stratford Avenue, Willow Grove, PA 19090; and Jillian C. Fesolovich, MSFS*, 2300 Stratford Avenue, Willow Grove, PA 19090

After attending this presentation, attendees will better understand using likelihood ratio software with their own internal validation data sets to gain new knowledge about genotyping systems as well as the effects that genetic analyzer injection time has on the likelihood ratio.

This presentation will impact the forensic science community by increasing the understanding of likelihood ratios and by explaining how increasing injection time affects the amount of information gathered and the probability of drop-out.

Internal validations of PowerPlex® 16 HS, PowerPlex® Fusion, and Identifiler® Plus amplification kits each produced large data sets containing five identical amplification replicates, with each sample injected at one, five, and ten seconds on a genetic analyzer. These validation data sets were utilized to obtain threshold values for the laboratory's interpretation guidelines. An empirical analytical threshold was derived by examining multiple negative controls for the highest non-artifactual peak, then multiplying the height of that peak by two. Lab Retriever, a freely available software program for the calculation of likelihood ratios, was used to calculate likelihood ratios of the validation sensitivity and mixture samples. This software program incorporates a Probability of Drop-Out, $P(Do)$, via an easy-to-use interface. Although a default $P(Do)$ calculator is readily available with the Lab Retriever software, it was desirable to determine $P(Do)$ calculators specific to each amplification kit and injection time for use in the laboratory, based on the laboratory's existing data. Using the validation data sets generated, along with calculations computed with Logic Drop, a logistic regression tool created in R-code, a system-specific algorithm was generated. This information was formatted into a user-friendly calculator, which was used to determine the $P(Do)$ for each sample in this study, based on the kit in which the sample was amplified and the injection time of the sample. The table below outlines values obtained from Logic Drop for the $P(Do)$ calculator for each kit studied:

	PowerPlex® 16 HS			AmpFISTR® Identifiler® Plus			PowerPlex® Fusion		
	1 Sec	5 Sec	10 Sec	1 Sec	5 Sec	10 Sec	1 Sec	5 Sec	10 Sec
Y-Intercept	7.2946	4.2663	3.0564	5.4327	4.2269	4.0238	7.0957	1.9859	0.9999
Slope	-0.071	-0.036	-0.026	-0.067	-0.049	-0.039	-0.104	-0.026	-0.016

In addition, $P(Do)$ was calculated by hand by dividing the number of alleles observed by the number of alleles expected and was compared to the $P(Do)$ calculated based on Logic Drop values. Likelihood ratios for single-source samples, two-person mixtures, and three-person mixtures were calculated for each race (Caucasian, African American, and Hispanic) and injection time (one, five, and ten seconds) to determine if there was any statistical difference between them. An analysis of variance was calculated from that data that indicates that increasing injection time does not provide a statistically significant increase in information as is commonly believed. Significant differences were only observed between one-second and ten-second injection times for an input DNA concentration of 250pg using the AmpFISTR® Identifiler® Plus typing kit. This information begs the question of whether increasing the injection time with the hopes of increasing the information in the sample will be beneficial.

Likelihood Ratio, Lab Retriever, Probability of Drop-Out

B188 Fabric Phase Sorptive Extraction Media: A Highly Effective Forensic Sample Collection and Storage Device

Abuzar Kabir, PhD, Florida International University, 11200 SW 8th Street, AHC4-215, Miami, FL 33199; Rodolfo Mesa, 6301 SW 163 Court, Miami, FL 33193; and Kenneth G. Furton, PhD, Florida International University, International Forensic Research Institute, University Park, Miami, FL 33199*

After attending this presentation, attendees will understand the working principle, advantages, and potential applications of the recently developed sample preparation technique known as Fabric Phase Sorptive Extraction (FPSE) in preparing forensic samples for instrumental analysis. The preparation capabilities of FPSE include extraction as well as storage.

This presentation will impact the forensic science community by proving that FPSE media can be used for the extraction of samples of forensic interest. Use of FPSE also reduces the collection steps involved in performing an extraction, therefore reducing the expensive labor and supply costs associated with collecting the sample from the field/crime scene and transporting it to the analytical laboratory before instrumental analysis begins.

FPSE has been shown to be a simple and more effective alternative to traditional, commercially available extraction techniques for preparing forensic samples for instrumental analysis and highly effective in extracting illicit drugs, nitroaromatic explosives, and other trace organic compounds of forensic significance directly from biological/environmental samples. The current study illustrates the application of FPSE in extracting and retaining eight compounds of interest from water. These compounds are: 3,4- and 3,5-dimethylphenol (compound class: phenols); Diphenylamine (DPA) and 2-Nitrodiphenylamine (NDPA) (compound class: amines); benzophenone and t-chalcone (compound class: ketones); and, phenanthrene and anthracene (compound class: Polycyclic Aromatic Hydrocarbons (PAHs)).

The two selected PAHs were included by the United States Environmental Protection Agency (U.S. EPA) in their Priority Pollutants List because of their carcinogenic properties. 3,4-dimethylphenol, 3,5-dimethylphenol, NDPA, and DPA are toxic to humans and wildlife which makes them relevant in the fields of environmental and criminal forensics. Benzophenone derivatives, such as benzophenone-3 which is commonly used in sunscreen products, have been found to be toxic and present serious ecological risks. Benzophenone and t-chalcone were chosen to represent ketones, which is a prevalent functional group in chemistry. Various methodologies have been developed and published over the years for sample preparation for the chemical analysis of these compounds. These methodologies have been based on techniques including, but not limited to, Solid Phase Extraction (SPE), Liquid-Liquid Extraction (LLE), Solid-Phase Microextraction (SPME), and Stir Bar Sorptive Extraction (SBSE).

Methods involving sample preparation by FPSE were developed for these eight compounds with each class treated separately because of the wide range of chemical properties within this group. The effects of extraction and desorption parameters such as extraction volume, extraction time, ionic strength, stirring rate, desorption time, and desorption solvent system on the extraction/desorption efficiency were investigated and optimized. FPSE was coupled to high-performance liquid chromatography with ultraviolet detection. The developed method was used for the determination of analytical merits: intra-day and inter-day repeatability, linearity, limit of detection and limit of quantitation. This method was also applied to extracting these compounds from spiked samples of water from a local pond and from reclaimed water. The optimized and validated FPSE methods were combined for extractions of the aforementioned group of eight compounds. Once these were extracted, the FPSE media were stored under refrigeration and desorption was done more than a month later with no loss of analytes.

FPSE addresses some important shortcomings of conventional extraction and microextraction techniques. For instance, extractions from pond and reclaimed water were done without any sample pretreatment such as filtration or centrifugation of the sample prior to extraction. FPSE utilizes a small flexible media coated with sol-gel hybrid organic-inorganic polymeric material as the extraction sorbent. The sol-gel coating process results in a highly porous polymeric network chemically bonded to the substrate surface. The hybrid material inherently possesses high thermal, chemical, and mechanical resistance as well as high specific surface area. Comparing to the primary contact surface area of 1,000mm² for FPSE vs. 100mm² for SBSE vs. 20mm² for SPME, FPSE is superior which translates into greater extraction efficiency of either of these techniques. The high primary contact surface area of FPSE media increases the probability of the successful sorbent-analyte interaction for an effective analyte extraction, resulting in fast extraction equilibria along with high preconcentration factor.

Retentive Characteristics, FPSE, Forensic Evidence

B189 Investigating the Use of Illicit Drug Smoke Aerosol Residues as Recoverable Trace Evidence

Julie L. Bitter, PhD, National Institute of Standards and Technology, 100 Bureau Drive, Mail Stop 8371, Gaithersburg, MD 20852*

After attending this presentation, attendees will understand how aerosol residues may provide a valuable form of forensic evidence in drug-related cases that is currently unused.

This presentation will impact the forensic science community by providing the first results of examining third-hand smoke aerosol residues from drug substances other than tobacco cigarettes. This presentation will add to criminalistics and trace evidence research by exploring the potential for expanding the types of drug evidence recovered from scenes when the contraband is not present.

Smoke aerosol residues, or third-hand smoke, from tobacco cigarettes has been highlighted in recent years as a silent and significant threat to the health and safety of indoor environments. These residues are the remnants of second-hand smoke that are deposited onto surfaces such as clothing, car interiors, countertops, tables, and chairs. Studies have demonstrated that these smoke residues and their degradation products on various interior surfaces can be collected and identified in areas of habitual smoking. Where these findings are especially important for health concerns, the studies performed with nicotine and other cigarette smoke alkaloids lend themselves to an untapped source of trace forensic evidence.

In this experiment, three commonly smoked illicit drugs were chosen and examined for their potential as recoverable smoke aerosols from idealized surfaces. Cocaine, heroin, and methamphetamine were made into useable standard solutions and a known mass was deposited onto a substrate and dried for 24 hours. These substrates were heated at various temperatures to volatilize the drug into a vapor and the resulting aerosol was collected either passively or under the influence of suctioning air flow onto a silicon wafer collector surface. The size of the aerosol particles was investigated using particle measurement instruments and the collection substrates were analyzed via electron microscopy to examine the physical state of the aerosol particles. Chemical analysis was performed using high-performance liquid chromatography, electrospray ionization/mass spectrometry, and direct analysis in real-time mass spectrometry to investigate the extent of pyrolytic degradation of each drug as a function of temperature. Experiments were also performed by introducing adulterant or substances in combination with the illicit drug to understand how impure street samples may undergo different volatilization processes.

Particle size measurements showed that greater than 90% of the aerosols generated were 1 μ m or less in size for both illicit and adulterant drugs examined. A trend toward smaller particle sizes was also seen with increasing temperature; however, a slightly larger average size was seen when an illicit drug was mixed with an adulterant. The increase in temperature also increased the concentration of degradation products formed from pyrolysis of the drugs, beginning around 400°C for most drugs examined.

This study examines the first steps toward the recovery of useful forensic evidence in drug-related offenses without having to have a drug sample, or even visible drug particles, present. Future work will expand on the current study pertaining to the illicit drugs studied and various combinations as well as recovery from surfaces encountered in buildings and vehicles and environmental effects.

Illicit Drugs, Residue, Aerosol

B190 Analysis of Phenethylamine Street Drugs for Psychoactive Compounds and Impurities

*Maura K. McGonigal**, 107 Whitmore Laboratories, University Park, PA 16802; *Philip Smith, PhD*, 323 Life Sciences Bldg, University Park, PA 16802; *Noelle Elliott, PhD*, Perkin Elmer, 710 Bridgeport Avenue, Shelton, CT 06484; and *Frank Dorman, PhD*, 107 Whitmore Labs, University Park, PA 16802

After attending this presentation, attendees will understand details concerning the challenges of separation and analysis of the various phenethylamine compounds and how the analysis of the reference materials differs from what is observed in actual street samples. Separation utilizing Ultra-High Performance Liquid Chromatography, coupled with Time-Of-Flight/Mass Spectrometry (UHPLC-TOF/MS) will be demonstrated along with a direct sample analysis approach utilizing Direct Sample Analysis (DSA)-TOF/MS.

This presentation will impact the forensic science community by discussing how discovering the impurities within these compounds and raising awareness of the dangers of consuming drugs from incompetent synthesis may prevent future overdoses and health complications and diminish the market for unsafe illegal drugs.

The purpose of this study is to determine not only the identity of the psychoactive compound(s) and their concentrations in the various street samples but also to determine impurities which may exist from less-than-ideal synthetic procedures likely employed by potential users/manufacturers of “2C-type” drugs. Serious health complications and fatal overdoses have brought phenethylamine designer drug use to the public’s attention. The phenethylamine compounds alone are not believed to be causing the health complications but rather the cause may be impurities within the sample. These impurities may result from the improper technique and inadequate equipment used during illegal synthesis. The substituents on these emerging drugs are constantly changed in order to avoid legal ramifications; however, many of these compounds are Schedule I drugs and, therefore, their analogs are also illegal according to the Federal Analog Act. These compounds are 2C-X-series analogs of mescaline. The name “2C” results from the two carbons in the ethyl chain. These synthetic drugs are marketed as having affects similar to LSD and are typically consumed sublingually via blotter paper. The compounds have psychedelic affects on the 5HT^{2A} receptor in the brain. The compounds have a variety of street names including “N-BOMB,” “Smiles,” and “Bromo-DragonFLY.”

The objective of this research is to qualitatively and quantitatively identify the drugs and potential impurities. Street samples were compared to known standards in order to determine if impurities exist that may be resulting in health complications. The analysis was done using a variety of UHPLC instruments. Liquid chromatography was utilized rather than gas chromatography because the 2C compounds are considerably more reactive than many other recreational drugs. Analysis by gas chromatography has proven troublesome, at best. Additionally, using gas chromatography would require derivatization, which generally utilizes aprotic solvents, which do not allow for dissolution of the 2C compounds. Following UHPLC separation, TOF/MS was employed for compound identification and subsequent quantification. Finally, a separate sample introduction technique (DSA) was coupled with TOF/MS, thus providing various methods of analysis and identification of the targeted drugs and impurities, which will all be compared and contrasted in this presentation.

MS/MS spectra were used to determine the fragmentation patterns; these fragmentation patterns were observed for 28 standards. The first fragment for every 2C compound was a loss of 17amu, representing the loss of the -NH₂ substituent. Compounds belonging to the NBOMe subgroup fragmented into a 121 peak. Halogenated compounds displayed the loss of a halogen group. The mass spectrum for every 2C compound includes a peak at 77m/z, which represents the phenyl ion, and a peak at 91m/z, which represents the tropylium ion. While all the MS/MS spectra for the compounds were similar in fragmentation patterns, they displayed differences that allow the analyst to distinguish which compound is present. Using a high-resolution MS instrument enables an analyst to determine the molecular formula of unknown compounds. The mass spectra generated after UHPLC separation and DSA of a blotter paper street sample were compared with the spectra of the 19 standards. Upon comparison, 25C NBOMe and 25B NBOMe were identified on the blotter paper. This identification was confirmed by comparing mass spectra fragmentation patterns and isotope ratios for chlorine and bromine from the street sample and the standards. Discovering the impurities within these compounds and raising awareness of the dangers of consuming drugs from incompetent synthesis may prevent future overdoses and health complications and diminish the market for unsafe illegal drugs. Because these drugs are emerging substances of abuse, there are no accepted protocols for analysis. DSA allows for a quick screening of seized compounds that can then be analyzed and identified using UHPLC-TOF/MS.

2C, Phenethylamines, DSA-TOF/MS

B191 Rapid Drug Identification in the Field Using Direct Analysis in Real Time (DART®) and a Portable Ion Trap Mass Spectrometer

Berk Oktem, PhD, MassTech, 6992 Columbia Gateway Drive, Ste 160, Columbia, MD 21046-2985; Kenyon M. Evans-Nguyen, PhD, 401 W Kennedy Boulevard, Tampa, FL 33606; Hilary Brown, 401 W Kennedy Boulevard, Tampa, FL 33606; and Vladimir Doroshenko, PhD, MassTech, Inc, 6992 Columbia Gateway Drive, Ste 160, Columbia, MD 21046-2985*

After attending this presentation, attendees will understand how a portable ion trap mass spectrometer coupled with DART® can be used for definitive drug analysis in the field. Attendees will learn the capabilities of the instrument, including how the use of multiple-stage tandem mass spectrometry (MS) can be used to differentiate closely related drugs.

This presentation will impact the forensic science community by demonstrating the DART® coupled to a portable ion trap mass spectrometer, a new tool that can provide rapid, accurate analysis of established and newer designer drugs in the field.

Identification and differentiation of the consistently evolving designer drugs being encountered by law enforcement is challenging established techniques in drug analysis. Color tests have been used as reliable presumptive field tests for some time but many newer phenylethylamine derivatives, cathinones, and synthetic cannabinoids yield false negatives when tested with these reagents. This is a particular challenge for law enforcement officials who need rapid characterization of substances purchased in undercover drug buys to validate that the substance is actually a controlled substance. Hand-held Raman spectrophotometers have become commercially available to address this issue and are a good replacement for presumptive color tests; however, they are not specific enough for definitive testing. The development of ambient ionization techniques for MS, including DART® ionization, have made it feasible to obtain mass spectra directly from drug evidence. Steiner and Larson validated the use of DART® coupled with a time-of-flight MS for reliable drug screening in the laboratory.¹ For the purpose of this research, DART® has been coupled with a portable ion trap MS to yield an instrument that can be used for definitive identification of drugs, without sample preparation, in the field.

Initial validation experiments were done in a laboratory setting using pure drug standards. The IonSense® DART® source was coupled with a MassTech® MT Explorer 50 ion trap MS, a self-contained instrument weighing 75 lbs. with dimensions of 12"x17"x20". Numerous drug standards were tested using both a compressed cylinder of nitrogen gas and an air compressor as the gas supply for the DART® source. Using nitrogen as the supply gas, the expected mass spectra and tandem mass spectra were obtained for all drugs tested. Air could be used for analysis of most compounds; however, some drugs, including methamphetamine, did not yield significant signal when air was used. Ozone, formed from the exposure of oxygen to the DART® plasma, was detected around the DART® source when the air compressor was used as the supply. It is likely that drugs that are significantly reactive with ozone were not detected because of their reaction with ozone.

After establishing a preliminary library of mass spectra and tandem mass spectra using drug standards, the instrumentation and a small canister of compressed nitrogen gas were transported to the Osceola County Sheriff's evidence room. The instrument was set up in ~15 minutes and was ready to function after vacuum was established (approximately 30 minutes). Numerous pieces of evidence including a cannabis leaf, "K2," cocaine, heroin, methamphetamine, an oxycodone tablet, and an alprazolam tablet were directly analyzed, yielding accurate results in real-time.

Current work is focused on studying closely related compounds to fully assess the specificity of this technique. The portable ion trap is lower resolution than the time-of-flight MSs previously used for drug analysis with DART® and cannot be used for accurate mass analysis. Additionally, accurate mass analysis cannot be used to differentiate isomers; however, ion traps can perform multi-stage tandem mass spectrometry and all the drugs tested were distinguished using MS2 spectra, except two closely related isomers, 5-APDB and 6-APDB. Currently, MS3 spectra are being acquired to determine further test the specificity of this instrumentation. Several compounds that are isomeric or isobaric with controlled substances and are also expected to yield similar MS2 spectra are being tested to see if for compounds with identical mass spectra (MS1 spectra) and similar MS2 spectra, the MS3 spectra will be sufficiently unique to differentiate them.

B192 Forensic Analysis of Dipyrone in Fentanyl Samples

Yuriy Uvaydov, MS*, 99 Tenth Avenue, Ste 721, New York, NY 10011

The goal of this presentation is to provide attendees with relevant information about a newly emerging trend of fentanyl samples encountered by the Drug Enforcement Administration (DEA). Attendees will also gain an insight of commonly encountered adulterants/cutting agents and the methodologies required for conclusive identification. These findings and methodologies may impact individuals in both the forensic science and toxicology fields.

This presentation will impact the forensic science community by highlighting some of the trends that are seen with fentanyl samples in the DEA Northeast Laboratory.

Fentanyl, N-phenyl-N-[1-(2-phenylethyl)-4-piperidinyl]-propanamide, is a synthetic opioid commonly used in anesthesia both as a pre-anesthetic and postoperatively to control pain.¹ It has an analgesic potency of approximately 100 times that of morphine and 50 times that of heroin.² Due to its potential for abuse, it is a Schedule II drug under the Controlled Substances Act. Illicit drug dealers often encounter difficulty when utilizing fentanyl as an adulterant due to its extremely high potency compared to other cutting agents. In 2013, the DEA Northeast Laboratory experienced a resurgence of heroin exhibits adulterated with fentanyl. This potent combination of dangerous drugs was attributed to an increase in overdose fatalities throughout the northeast region.

In an effort to maximize the effects of the drug, illicit dealers add additional adulterants which have synergistic effects in combination with fentanyl samples. Dipyrone, a methanesulfonic acid sodium salt of aminopyrine, is a relatively new adulterant that has been commonly seen in fentanyl cases in the northeast region. On its own, dipyrone exhibits analgesic effects on the body and is also commonly used to control pain; however, due to its potential fatal side effects, it has been withdrawn from medical use in the United States. Forensic analysis of dipyrone utilizing conventional methodologies such as gas chromatography/mass spectrometry and gas chromatography/flame ionization detector may yield a false positive for the presence of aminopyrine. Electrospray Ionization-Liquid Chromatography/Mass Spectrometry (ESI-LC/MS) has shown to have high discriminatory power and the required sensitivity for the conclusive identification of dipyrone and other adulterants in illicit fentanyl exhibits.

In this study, two ESI-LC/MS methods will be presented for routine confirmation of dipyrone in fentanyl-seized samples. Preliminary results showed that dipyrone and aminopyrine can be confirmed in positive mode ESI based on C18 chromatographic separation and unique fragmentation for each compound. The results also revealed that positive mode ESI will not detect the pseudomolecular ion for dipyrone but will for aminopyrine. In order to detect the pseudomolecular ion, one must employ negative mode ESI-LC/MS. Both methods employed the use of a C18 stationary phase and a quaternary pump.

Dipyrone, Fentanyl, LC/MS

B193 The Utility of Ultra High-Performance Liquid Chromatography With Time-of-Flight Detection for the Identification of Synthetic Cannabinoids: Part I — The Role of the Separation Technique

Ira S. Lurie, PhD, George Washington University, Dept of Forensic Science, 2100 Foxhall Road, NW, Somers Hall, Lower Level, Washington, DC 20007; Ioan Marginean, PhD, George Washington University, 2100 Foxhall Road, NW, Somers Hall L14C, Washington, DC 20007; and Walter F. Rowe, PhD, George Washington University, Dept of Forensic Science, 2100 Foxhall Road, NW, Washington, DC 20007*

After attending this presentation, attendees will understand some principles of Ultra High-Performance Liquid Chromatography (UHPLC), in particular how to develop a separation for a complex mixture. In addition, attendees will gain insights into the differences between UHPLC and capillary Gas Chromatography (GC) for the separation of synthetic cannabinoids, including structural isomers.

This presentation will impact the forensic science community by clarifying the role of UHPLC in aiding in the identification of highly similar solutes, such as synthetic cannabinoids, that are present in emerging drugs.

Separation techniques are an integral part of forensic drug analysis toolbox for both screening and confirmation purposes. The Scientific Working Group for the Analysis of Seized Drugs (SWGDRUG), which is responsible for setting standards for drug analysis, requires a category A test such as Mass Spectrometry (MS) with an additional test from either category B or C. If a category A method is not used, two uncorrelated techniques from category B and one from category C must be included, from which separation techniques such as capillary electrophoresis, gas chromatography, liquid chromatography, and thin layer chromatography would qualify. In addition, even if a technique such as GC/MS is used, an additional identification test is highly desirable for increased confidence of analysis and quality assurance purposes. Methodology capable of resolving a host of similar compounds is required, especially in the case of emerging drugs. In this vein, UHPLC offers relatively high resolving power and is well suited for this purpose. Besides the ability to separate controlled substances of a particular class of seized drugs, such as the synthetic cannabinoids, the utility of UHPLC depends on the capability of distinguishing between structural isomers and certain stereoisomers. The latter is particularly important since the controlled substances can have both controlled and non-controlled isomers. Distinguishing compounds based on retention time becomes particularly important when the solutes have identical mass spectra. UHPLC-Time Of Flight (TOF)/MS and GC/MS separations are compared for 23 out of the 25 controlled synthetic cannabinoids. For UHPLC reversed phase chromatography with three 2.7 μ m 2.1x 150mm columns containing superficially porous stationary phases, including C18, Phenyl-Hexyl, and pentafluorophenylpropyl (PFP) are used, while for capillary GC a 0.25 μ m 0.25mm x 30m Elite-5MS (equivalent to DB-5, HP-5) capillary column is employed. Superficially porous particle columns (i.e., 2.7 μ m particles) offer UHPLC performance with significantly lower back pressure than fully porous \leq 2 μ m particle columns. For UHPLC "optimum" isocratic or gradient separations are obtained with 0.1% formic acid as the base solvent by varying the amount of acetonitrile or methanol, changing the time of the gradient and varying the temperature. For a gradient separation using a Phenyl-Hexyl column, 19 out of 23 solutes are resolved (resolution \geq 1), including two pairs of diastereomers (CP47, 497 and epi CP47, 497; CP47, 497-C8 and epi CP47, 497-C8) and a pair of structural isomers (JWH-019 and JWH-122) employing acetonitrile as the strong solvent at 35°C. The unresolved solutes are resolved using alternative chromatographic systems, employing either GC or a UHPLC (C18 or PFP stationary phase), which separate 15, 17, and 14 out of the 23 controlled synthetic cannabinoids, respectively.

For the separation of a controlled synthetic cannabinoid JWH-018 and nine of its structural isomers, using the same chromatographic conditions for the 23 solutes above, capillary GC, and the three UHPLC stationary phases Phenyl-Hexyl, C18 and PFP resolved 4, 0, 3, and 3 compounds, respectively. For the four systems investigated, only UHPLC with the PFP stationary phase resolved JWH-018 from the other structural isomers

The degree of orthogonality of the various chromatographic systems is demonstrated using multivariate analysis.

Synthetic Cannabinoids, UHPLC, SWGDRUG

B194 The Utility of Ultra High-Performance Liquid Chromatography with Time-of-Flight Detection for the Identification of Synthetic Cannabinoids: Part II — The Role of the Detection Technique

Ioan Marginean, PhD, George Washington University, 2100 Foxhall Road, NW, Somers Hall L14C, Washington, DC 20007; Ira S. Lurie, PhD, George Washington University, Dept of Forensic Science, 2100 Foxhall Road, NW, Somers Hall, Lower Level, Washington, DC 20007; and Walter F. Rowe, PhD, George Washington University, Dept of Forensic Science, 2100 Foxhall Road, NW, Washington, DC 20007*

After attending the presentation, attendees will understand the advantages and disadvantages of using a Time-Of-Flight (TOF) high resolution mass spectrometer as detector following separation by Ultra High-Performance Liquid Chromatography (UHPLC) as compared to the traditional capillary Gas Chromatography-Quadrupole Mass Spectrometry (GC/MS). Attendees will also be exposed to the differences between classical electron-impact mass spectra and those of electrospray ionization mass spectra with and without in-source fragmentation.

The presentation will impact the forensic science community by further exploring the role of high resolution mass spectrometry in the identification of forensic drugs. Examples will include analyses of emerging drugs such as synthetic cannabinoids and some of their isomers.

The Scientific Working Group for the Analysis of Seized Drugs (SWGDRUG) classified mass spectrometry in the category A (highest discriminating power), with the exception of techniques that only produce molecular weight information. The SWGDRUG recommendations do not specifically address the issue of high-resolution mass spectrometry, as it is addressed by other similar groups (e.g., the recommendations of Scientific Working Group for Forensic Toxicology (SWGTOX)). This research tackles the role of high-resolution mass spectrometry in the context of the analysis of synthetic cannabinoids.

Currently, there are 25 synthetic cannabinoids on the list of controlled substances by the Drug Enforcement Administration and more synthetic cannabinoids are likely to become controlled in the future. A mixture of 23 controlled synthetic cannabinoids was subjected to analyses by GC/MS using a 0.25 μ m 0.25mm x 30m Elite-5MS capillary column (equivalent to DB-5, HP-5) and UHPLC-TOF/MS with three 2.1 x 150mm columns packed with 2.7 μ m superficially porous stationary phases (C18, Phenyl-Hexyl, and pentafluorophenylpropyl (PFP)). The analyses were also performed on a mixture of ten positional isomers of JWH018 to assess their identification in potentially complex mixtures.

The mass spectra resulted from the GC/MS experiments showed a high degree of specificity with the exception of diastereoisomers (CP47, 497 and epi CP47, 497; CP47, 497-C8 and epi CP47, 497-C8); however, all chromatographic systems were able to separate these diastereoisomers. The ten positional isomers of JWH018 were also easily distinguishable based on their mass spectra.

The masses measured by UHPLC-TOF/MS experiments were generally within a few ppm of the accurate mass of the synthetic cannabinoids. Measurement of the accurate mass can bring an increased level of confidence to a forensic analysis. Mass spectra using in-source fragmentation brought additional information regarding the analytes; however, the fragmentation pattern did not have the degree of specificity observed in GC/MS experiments. Especially in the case of JWH018 isomers, where the difference between compounds was mostly limited to a side alkyl chain, the mass spectra did not include specific peaks allowing differentiation between compounds. Although all solutes could be uniquely identified by GC/MS, UHPLC-TOF/MS provides a highly orthogonal technique that greatly enhances the confidence in the analysis.

Synthetic Cannabinoids, High Resolution MS, Forensic Drugs

B195 High-Sensitivity Drug Analysis With Optical Isomer Resolution Using Mixed Chiral Selectors

Christopher M. Rollman, BS, George Washington University, 2100 Foxhall Road, NW, Somers Hall, L14, Washington, DC 20007; and Mehdi Moini, PhD, George Washington University, Dept of Forensic Sciences, 2100 Foxhall Road, NW, Washington, DC 20052*

The goal of this presentation is to discuss the application of mixed chiral selectors to the separation of drugs and their optical isomers using highly sensitive Capillary Electrophoresis/Mass Spectrometry (CE/MS) in approximately 20 minutes.

This presentation will impact the forensic science community by describing how to use this rapid and highly sensitive method to separate and identify isomers of commonly encountered drugs of abuse such as amphetamine and methamphetamine.

The separation of drug isomers is essential since scheduling and sentencing could vary based on which isomer of a compound is present in a sample. Several techniques are currently used for the separation and detection of optical isomers including Gas Chromatography/Mass Spectrometry (GC/MS), Capillary Electrophoresis/Ultraviolet (CE/UV), and Liquid Chromatography/Mass Spectrometry (LC-MS). The drawbacks of these techniques are the use of expensive chiral columns (GC/MS and LC/MS), derivatization of the sample (GC/MS), and low sensitivity and specificity (CE/UV). To address these deficiencies, a highly sensitive CE/MS technique has been developed for the separation and detection of drugs and their optical isomers in about 20 minutes using only 1 nanoliter of the solution. The technique is faster and is almost 1,000x more sensitive than current GC/MS and LC/MS techniques. In addition, it provides base-line separation of the optical and positional isomer in one run. The superior properties of this technique are due to three unique characteristics of this design: (1) the new CE/MS uses a porous tip for interfacing CE to MS. A porous tip allows narrow capillaries (<20 μ m-i.d.) to be interfaced to MS allowing maximum sensitivity under electrospray ionization without introducing any dead volume and consuming only one nanoliter of the sample solution; (2) the use of 18-crown-6 as a complexation reagent in the CE background electrolyte — the sensitivity of the amine-containing compounds are enhanced due to high ionization efficiency of the complexes; and, (3) the addition of the chiral selector (+)18-crown-6-tetracarboxylic acid not only allows for higher sensitivity but also separation of the optical isomers of compounds containing primary amines; however, the optical isomers of secondary amines such as methamphetamine were not baseline separated. To separate all amines, (+)18-C-6-TCA was mixed with several types of cyclodextrins (α -, β -, γ -cyclodextrin) to examine the optimum background electrolyte for CE/MS analysis drugs and their optical isomers. Using a mixture of (+)18-C-6-TCA and β -cyclodextrin was found to baseline separate (\pm)-amphetamine and (\pm)-methamphetamine mixture in less than 20 minutes. To speed up the analysis, this recently developed ultrafast CE-MS is being applied to the analysis of drugs and their positional and optical isomers in approximately 60 seconds.

Using a background electrolyte containing both 18-C-6-TCA and cyclodextrin provides enhanced separation and sensitivity over a background electrolyte of the individual chiral selectors.

Drug, Chiral Separation, CE/MS

B196 Determination of the Stoichiometry in the Modified Ferric Hydroxamate Test for Gamma-Hydroxybutyric Acid (GHB)

*Thomas A. Brettell, PhD**, Cedar Crest College, 100 College Drive, Allentown, PA 18104; and *Karen Lau*, 1689 32nd Street, SW, Allentown, PA

After attending this presentation, attendees will understand how the method of continuous variation and mole ratio method, utilizing Ultraviolet/Visible (UV/Vis) spectrophotometry, can be used for the determination of the stoichiometry of the purple-colored metal-ligand complex formed in the modified hydroxamate test for GHB.

This presentation will impact the forensic science community by providing an understanding of the mechanism and final structure of the complex that forms in the modified ferric hydroxamate test for GHB.

A rapid color test was developed to detect GHB in human urine in 2002. The test involves converting GHB to Gamma-Butyrolactone (GBL) with acid followed by a ferric hydroxamate reaction with a monohydroxamic acid intermediate. A purple-colored complex with a 3:1 stoichiometry of drug ligand to iron metal was proposed and formed at pH 3; however, results of multiple, previous monohydroxamic acid studies contradicted that finding. Two of the previous studies found a 1:1 stoichiometry between a monohydroxamic acid ligand and iron metal ion and that the complex forms the most intense color at approximately 510nm below a pH of 2. The goal of this study was to further investigate the modified ferric hydroxamate test for GHB.

The methods of continuous variation and mole ratio were used to determine the stoichiometry of the purple complex formed in the modified ferric hydroxamate test for GHB. GBL was used as the starting material for research purposes. The monohydroxamate acid intermediate was formed after the addition of 0.5M hydroxylamine hydrochloride in 95% ethanol and 6M sodium hydroxide. The purple complex formed after the addition of iron (III) chloride and an adjustment of pH using 6M hydrochloric acid. UV/Vis spectrophotometry was used for the analysis and absorbance values were collected at 500nm (I_{MAX} of the complex). Studies of pH were performed by adding 0.2 mL and 0.1mL increments of hydrochloric and sulfuric acids to observe at what pH the complex is formed. Concentration studies were also performed to determine figures of merit including Limit Of Detection (LOD), Limit Of Quantitation (LOQ), Linear Dynamic Range (LDR), and molar absorptivity of the complex (ϵ). These studies were also repeated using lactones of different ring sizes, Beta-Butyrolactone (BBL) and Delta-Valerolactone (DVL). The effect of ionic strength by the addition of sodium chloride was also studied. Lastly, the modified ferric hydroxamate test was analyzed using GHB as the starting material.

It was determined that the purple complex formed in the modified ferric hydroxamate test had a 1:1 stoichiometry of drug ligand to iron metal. This stoichiometry was consistent with GBL, BBL, and DVL. The results of the pH study indicated that the complexes do not form until the pH was below 2. This result was achieved using two different acids with two different concentrations. Results from a concentration study for GBL indicated a LOD of $7.7 \times 10^{-4}M$, LOQ of $1.4 \times 10^{-3} M$, LDR of 1.4×10^{-3} - $5.0 \times 10^{-2}M$, and ϵ of 352.2 Liters/mol \times cm. The ionic strength studies indicated that the decrease in pH using an acid, not just the addition of chloride ions, was crucial to the formation of the purple complex. Preliminary results from the application of GHB to the modified ferric hydroxamate test indicated that it might not be necessary to add acid for the last step if enough acid was used to convert a sample containing GHB to GBL.

It is important for forensic chemists to understand the chemistry behind this color test because it reinforces validity of their results. Furthering the research behind the modified ferric hydroxamate reaction for GHB may allow for its future use in crime laboratories.

Stoichiometry, GHB, GBL

B197 An Analysis of Elemental Content in Various Brands of Cigarette Ash by Atomic Absorption Spectroscopy

Kaitlin E. Hafer, BS*, Cedar Crest College, 100 College Drive, Allentown, PA 18104; and Lindsey A. Welch, PhD, Cedar Crest College, 100 College Drive, Dept of Chemical and Physical Sciences, Allentown, PA 18104

After attending this presentation, attendees will understand the value of elemental analysis of cigarette ash when cigarette butts yield no DNA profiles. Attendees will learn that atomic absorption spectroscopy, a less sensitive but less costly instrument, can provide results consistent with those obtained using inductively coupled plasma methods.

This presentation will impact the forensic science community by showing that the analysis of cigarette ash can provide additional information for use at a crime scene.

Very little work exists studying the ash produced by cigarettes to benefit forensic science. This study quantified element concentrations in cigarette ash to investigate the ability to distinguish American cigarettes through four comparisons: inter-brand, intra-brand, menthol/non-menthol, and pack. To obtain cigarette ash, a “smoking apparatus” including a vacuum pump was built to simulate smoking a cigarette. Approximately 100mg of ash was digested in 2mL of concentrated HNO₃ followed by the addition of 2mL of concentrated HCl. Trace metal grade standards were used to generate calibration curves with concentration ranges in parts per million (ppm) using a Buck Scientific® Accusys 211 Atomic Absorption Spectrophotometer (AAS). Three elements (potassium (K), calcium (Ca), and magnesium (Mg)) were chosen due to producing the highest intensity values when analyzed via scanning electron microscopy-energy dispersive spectroscopy. Zinc (Zn) was also chosen based on elements studied in previous similar studies. Using Linear Discriminant Analysis (LDA) and the four previously mentioned metals, comparisons of inter-brand, intra-brand, and menthol/non-menthol cigarettes were performed.

Within the inter-brand study, Parliament® (PM), Newport® (NP), Camel Blu® (CB), and Marlboro® Red (MMR) cigarettes were compared. When the concentrations of each element were plotted against one another, Mg compared to Ca provided the most distinct clustering of points. In an LDA plot, it was found that separation occurred between the clusters of PM, NP, and CB brands. This was consistent with a previous similar study utilizing inductively coupled plasma-atomic emission spectroscopy.¹ Although brand clustering was observed, the LDA model generated was not sufficient for complete discrimination.

In the intra-brand study, Marlboro® Green (MGr), Marlboro® Gold (MG), Marlboro® Blue (MB), Marlboro® Black (MBK), and Marlboro® Smooth (MS) were compared. Element plots showed that, when compared, Ca and K displayed the most clustering among the cigarette brands. This finding supports the results observed in another study comparing element concentrations in cigarette material.² In the LDA plot, there was more overlap observed between brands in the intra-brand study, which was expected; however, the LDA plot indicated that complete discrimination could not be achieved.

For the menthol/non-menthol comparisons, Ca plotted against K displayed the most separation between the two groups. In regard to the pack comparisons, a nested Analysis Of Variance (ANOVA) was performed to determine if the variance seen between packs of the same brand affect the variances observed between different brands. All four elements produced a significant effect on pack variance; however, variance between packs of brands was not enough to affect the variance between brands. Overall, Mg, Ca, and K provided the most information for comparison purposes. Although the results are consistent with previous studies, analyzing the composition of the cigarettes based on the four elements selected does not produce LDA models with the ability to discriminate between brands. The analysis of additional elements could potentially aid in doing so.

Forensic Science, Atomic Absorption Spectroscopy, Cigarette Ash

B198 Forensic Source Attribution Using Stable Isotopes: Hairs to Humans and Insects to Carrion

*Glen P. Jackson, PhD**, West Virginia University, Dept of Forensic and Investigative Science, 208 Oglebay Hall, Morgantown, WV 26506-6121; *Kateryna Konstantynova*, 1056 Van Voorhis Road, K416, Morgantown, WV 26505; *Mayara P.V. De Matos, MS*, West Virginia University, 208 Oglebay Hall, Morgantown, WV 26506-6121; and *Rachel M. Mohr, PhD*, Dept of Forensic & Investigative Sci, 1600 University Avenue, Morgantown, WV 26506

After attending this presentation, attendees will understand how stable isotope ratio measurements can be used to: (1) provide physical and characteristic traits about donors from their hair, such as body mass index and age; and, (2) link different life stages of blow flies to their larval food source.

This presentation will impact the forensic science community by providing examples of objective chemical measurements and statistical classification methods for comparing human hairs with the traits of the donors. In addition, this presentation will provide an example of an instrumental method of analysis for predicting the food (carrion) source of blow fly larvae, pupae, and adult flies.

Although Isotope Ratio Mass Spectrometry (IRMS) has historically been considered a specialized technique requiring significant training and expertise, modern instruments provide such automation and ease-of-use that it is becoming more user friendly and a more common tool for answering a variety of forensic, ecological, geological, anthropological, and environmental questions. In the forensic community, IRMS is already in use in many government forensic laboratories and has passed *Daubert* standards for admissibility in court on many occasions. This presentation provides two studies involving source attribution using IRMS.

In the first part of the presentation, two different methods will be presented to classify and attribute human hair to subject groups such as body mass index, age, and sex. One method uses the absolute abundance of the amino acids in human hair, as determined by derivatization Gas Chromatography/Mass Spectrometry (GC/MS). Using this method, the classification model Fuzzy Rule Expert System (FuRES) can predict age or body mass index with better than 90% and 80% success rates, respectively. The second approach uses bulk and amino acid-specific isotope analysis as input variables for classification. Both methods of amino acid analysis required the analysis of 14 amino acids that were released from the hair following acid hydrolysis. Unlike GC/MS, the liquid chromatography/IRMS measurements did not require derivatization prior to analysis. Statistical techniques such as Canonical Discriminant Analysis (CDA) are used to overlook the covariance of amino acid values between individuals caused by dietary factors and instead highlight the selective differences caused by grouping factor(s) such as age, body mass index, and sex. For example, using leave-one-out cross-validation, CDA is able to predict the body mass index of a donor's hair sample with an approximately 80% success rate. Age group can be predicted with an approximately 87% success rate using leave-one-out cross-validation.

The second part of the presentation uses isotope ratios to link blow fly larvae, pupae, and adult flies to different food (carrion) sources. Ecologists often use isotope ratio analysis to determine the trophic level of organisms and their primary food sources; however, such analyses are rarely interested in linking adult insects to a specific meat source in a forensic context. This study presents a proof-of-concept study to test the hypothesis that adult blow flies can be linked to specific food sources via their stable isotope ratios. The results indicate that whereas carbon does not undergo systematic fractionation between carrion source, larvae, pupae, and adult flies, nitrogen undergoes significant fractionation (toward ^{12}C enrichment) at each lifecycle providing a total enrichment of approximately six per mil relative to the source carrion.

Hair Analysis, Isotope Ratios, Forensic Entomology

B199 From Plants to Projectiles: New Analytical Approaches to the Utility of Direct Analysis in Real Time (DART®) Technology in Forensic Cases

*Adam B. Hall, PhD**, Northeastern University, 140 The Fenway, Rm 421, 360 Huntington Avenue, Boston, MA 02115; *William Edison, MS*, Boston University School of Medicine, 72 E Concord Street, Boston, MA 02118; *Crystal N. Hart*, 93 Watertown Street, Watertown, MA 02472; *Rachel Underwood, MSFS*, Boston Police Department Crime Laboratory, 1 Schroeder Plaza, Boston, MA 02120; *Peter J. Diaczuk, BS*, 445 W 59th Street, New York, NY 10019-2925; *Joseph H. LaPointe, BSc*, IonSense, Inc, 999 Broadway, Ste 404, Saugus, MA 01906; and *Brian Musselman, PhD*, 999 Broadway, Saugus, MA

After attending this presentation, attendees will better understand two new applications of Direct Analysis in Real Time Mass Spectrometry (DART®-MS) technology in forensic science for the characterization of trace evidence off the surface of spent projectiles as well as the characterization of psychoactive compounds from interesting plant-based drugs of abuse.

This presentation will impact the forensic science community by demonstrating the applicability of DART® technology, a rapid, ambient ionization technique for relevant evidentiary materials in forensic cases from plants to projectiles.

This two-part presentation will address new application areas of DART®-MS: non-destructive characterization of trace evidence from the surface of projectiles and the evaluation of DART®-MS as a rapid analytical technique for the characterization of non-traditional, plant-based drugs of abuse. The purpose of the first part of this study was to examine the feasibility of trace material identification from the surface of spent bullets using DART®. The goals of the second part of this research were to develop methods for the analysis of a wide variety of plant-based drugs of abuse and to apply these methods in an effort to differentiate between multiple strains of seed species.

The examination of trace amounts of intermediate target materials collected on the surface of spent projectiles provides crucial information for trajectory reconstruction. Determining the origin of an unknown material adhered to a spent bullet allows for the identification of intermediate targets the bullet either contacted or penetrated during flight. Although significant information can be obtained, this aspect of trajectory reconstruction is often ignored. The ability of different bullet types to collect trace materials from intermediate targets and the ability to associate these materials to their origin was examined using microscopy and DART®-MS. Full metal jacket, jacketed hollow point, and lead round nose bullets were fired into sheets of five different commonly used building materials. All spent bullets were examined and photographed using a stereomicroscope. The spent bullets were then examined using DART®-MS to determine if any ion profiles generated from the trace materials could be associated with those of the intermediate target building materials through which the bullets were fired. The collection of trace from all five types of building materials was highly dependent on the type of bullet. The trace materials collected produced unique and interpretable ion profiles. Additionally, MS data from four of the five building materials tested matched the MS data generated from trace material collected on bullets from the respective target materials.

For the second part of this study, 12 different seed species reported to have psychoactive effects on the user were obtained and analyzed. Many plant species around the world are known to contain various psychoactive compounds. Due to their effects when consumed, many of these plants are used as a part of religious and ritualistic practices in many different cultures. As with any psychoactive compounds, these plants have the potential to be used in a recreational manner. In the United States, plant-based drugs of abuse, such as marijuana, have become commonly abused substances. Although the federal government currently regulates marijuana, many of the plant materials containing potential drugs of abuse are not regulated and can be purchased legally from various online sources. Physical examination was performed, in which average measurements were obtained to describe the length, width, thickness, and mass of each seed species, followed by DART®-MS analysis. The seeds were prepared for analysis by DART®-MS by grinding to homogenize the seed and embedding the powder onto QuickStrip™ cards. To optimize the method for analysis, three different DART® carrier gas temperatures were investigated for each sample by considering the signal to noise ratio, ion abundance, and presence of the analyte of interest at each source temperature using a single quadrupole mass spectrometer. The analytes detected were then subjected to MSⁿ fragmentation in a quadrupole ion trap mass spectrometer to confirm the identity of the analytes being detected. Fragmentation patterns were then compared to known fragmentation patterns reported within the literature, by other ionization methods such as: chemical ionization, atmospheric pressure chemical ionization, and electrospray ionization.

Forensic Chemistry, DART®-MS, New Approaches

C1 Large-Scale, Common-Source Identification of Digital Camera Images

Zeno J. Geradts, PhD*, *Netherlands Forensic Institute, Ministry of Justice, Laan van Ypenburg 6, Den Haag, SH 2497 GB, NETHERLANDS*; and Floris Gisolf, MSFS, *Laan van Ypenburg 6, Den Haag 2497 GB, NETHERLANDS*

After attending this presentation, attendees will be aware of a method for large-scale, common-source identification of a digital camera with possibilities to improve the speed of identification.

This presentation will impact the forensic science community by showing that large-scale camera identification is possible on a standard desktop computer in forensically relevant time while still maintaining a high degree of accuracy.

Photo Response Non-Uniformity (PRNU) noise, present in images made by a digital camera, can be used to identify the source camera of an image or link images with a common source. PRNU is caused by imperfections of image sensors during the manufacturing process. Due to these imperfections, each pixel on a camera sensor gives a slightly different signal, even when receiving the same amount of light. PRNU noise is systematic, meaning that it is approximately the same for every image made by a specific camera. Therefore, it can be used to identify the source camera of an image.

Many cases, such as child pornography cases, have large numbers of images (>10,000) from unknown sources. To identify a common source between these images, all the images have to be compared to one another. For example, a case with 10,000 images results in approximately 50 million comparisons. Using the original method, it would take roughly one year of computation time on a desktop computer with a 2.3 GHz quad core Central Processing Unit (CPU). For practical purposes, this is too long; therefore, two methods have been proposed in the past to decrease the computation time of camera identification.

The first method is to reduce the number of pixels used for the comparison of the PRNU patterns. Instead of taking all pixels of an image, only a percentage of the pixels are selected. The second method reduces the bits per pixel to store the data. Both methods reduce the information and, therefore, the computation time needed for the camera identification process. Applying these methods to a case with 100,000 images reduces the calculation time to approximately one day instead of one year; however, these methods were designed for cases where a suspect device is available to generate high-quality PRNU noise patterns.

Experiments on single-image comparison showed that applying these methods results in a low sensitivity: approximately a true positive rate of 0.65 at an experimental false positive rate of zero. To counter the negative effects of reducing the information, an algorithm was developed. This algorithm increases the sensitivity to approximately 98% at a small fraction of the total calculation time.

The idea behind the algorithm is that the PRNU noise pattern becomes clearer when multiple images of the same camera are used to estimate the PRNU noise pattern. The assumption is that the two images with the highest correlation above a certain threshold have a common source. The PRNU noise pattern of these images is then averaged for a clearer pattern. More images are added to this pattern, if their correlation with this averaged pattern is above the threshold. Images that would normally fall below the threshold, even though they are from the same source, are now added to the averaged pattern; while other images (originating from a different source) that were above the threshold by random chance, are now excluded.

This package of methods allows for large-scale, common-source identification on standard desktop computers, available to any forensic scientist, in a reduced amount of time.

This method can be combined with the quantization tables in JPEG files as a pre-selection measure as well as using Graphics Processing Units (GPUs) to improve the speed with larger databases of child pornography cases. Practical results of a large database of images are presented.

C3 Assessing the Relationship Between Individual Differences and Child Pornography Image Preferences in an Internet Sample of Child Pornography Consumers

Kathryn C. Seigfried-Spellar, PhD, University of Alabama, 410 Farrah Hall, Box 870320, Tuscaloosa, AL 35487*

After attending this presentation, attendees will have a better understanding of the relationship between child pornography image preferences and personality characteristics.

This presentation will impact the forensic science community by assessing whether personality characteristics are significantly related to the types of images preferred by internet pornography users. The preferred type or genre of images, rather than the collection itself, may provide researchers with a better understanding of the personality characteristics associated with child pornography use.

Internet child pornography is not only a global epidemic, it is one of the fastest growing crimes in the United States. According to the Federal Bureau of Investigation, the United States has seen a 2,500% increase in the last ten years in the number of child pornography arrests. What drives someone to collect different genres of pornography is unknown; however, one thing is for certain, the collections of child pornography users are vastly different. According to Taylor et al., child pornography should be considered as a wide range of images, which involve different levels of child victimization (e.g., innocent vs. erotic, posing vs. sadistic).¹

In general, research suggests that the majority of offenders are collecting images of young children with higher levels of child sexual victimization (e.g., sexual penetration, sadistic violence).^{2,3} For example, the Child Exploitation and Online Protection Centre reported an increase in the number of non-commercial sources depicting babies and toddlers in child sex abuse images, as well as an increase in the number of images depicting children of different racial backgrounds and locations, such as South America and South Korea.^{4,5} In addition, the United Kingdom's Internet Watch Foundation reported an increase in the number of commercial websites depicting severe forms of child sexual abuse with more than half (69%) of the child victims appearing to be under the age of ten years.⁶ Of those images, 24% appeared to be under the age of six years and 4% of the child victims appearing to be to be under the age of two years.⁶

The preferred type or genre of images, rather than the collection, may provide researchers with a better understanding of the personality characteristics associated with child pornography use; however, this link between individual differences (e.g., extraversion) and types of images (e.g., age of child, sadistic vs. erotic) collected by child pornography users has yet to be simultaneously analyzed.⁷ Therefore, the current study will be the first to assess whether personality characteristics are significantly related to the types of images preferred by internet pornography users. The specific goal of this study was to determine if certain personality characteristics were predictive of certain child pornography image preferences.

This study was conducted electronically using an anonymous, internet-based survey in order to sample child pornography users from the "general population of internet users" rather than the clinical or forensic population. Respondents were solicited from the website Mechanical Turk[®]; research studies have shown Mechanical Turk[®] may be used to obtain high-quality data inexpensively and rapidly from a diverse participant pool and it provides better generalizability than snowball sampling procedures.^{8,9}

For the current study, more than 1,000 respondents completed the anonymous internet-based survey. The results and future implications of the study's findings will be discussed.

Internet Child Pornography, Personality, Child Sex Abuse Images

C4 Forensic Image Comparison of Feet

Zeno J. Geradts, PhD*, Netherlands Forensic Institute, Ministry of Justice, Laan van Ypenburg 6, Den Haag, SH 2497 GB, NETHERLANDS; and Katerina Palla, MFS, NFI, Laan van Ypenburg 6, Den Haag, AE 24979, NETHERLANDS

The goal of this presentation is to develop a biometric method (observation checklist) for foot comparison via images. On recordings of certain crimes, such as child abuse situations, the face is not always (properly) shown, unlike other body parts such as the feet. In such cases, feet can offer a solution for identifying the perpetrator. Therefore, the need has arisen to develop a method for the identification of people based on images of their feet.

This presentation will impact the forensic science community by providing a framework for foot comparison which can be used in casework.

To be able to evaluate the proposed method, a Netherlands Forensic Institute (NFI) foot database of images (left and right feet) was created. The NFI foot database of images consists of 52 subjects (19 females and 33 males). Eight photographs, four of each foot, were extracted from each subject; the four photographs were from different sides.

During the project, a study was performed to evaluate the potential of using numerical features for the observation checklist. The dispersion was observed to conclude which numerical features would be good individualizing factors. Ten out of sixteen features were dispersed enough to be used in the observation checklist (standard deviation >0.04). The repeatability and reproducibility of the model was studied and it was concluded that the length ratios of the toes have the smallest values. Another factor studied for the applicability of the numerical features was the foot's daily changes; the toes' length ratios have the smaller daily change.

The proposed identification checklist has the potential to be effective on actual cases of perpetrator identification. The accuracy of the tests is always above 90%, with the highest score being 98.34% of the top-side test and the lowest being 90.30% of the poor quality test. Furthermore, it was observed that the use of the proposed method improved the results by an average of 10% compared to not using it.

A probability format was suggested as a means for reporting. As the checklist consists of morphological features which are very distinctive for the comparison and scientists have not found a way to calculate the Likelihood Ratio (LR) from non-numerical features, the needed ratio cannot be estimated; however, a statistical analysis was performed to check the potential of reporting with LR for the suggested numerical features. Again in the bivariate analysis, the combination of toe length ratios gave maximum probability densities compared to the other combinations. In addition, the larger LR for a specific case was calculated on the sole-side image from which six numerical features can be extracted.

To conclude, although the proposed identification checklist has all the potential to be used on actual cases of perpetrator identification from foot imagery, more research is recommended.

Feet Comparison, Image, Biometric

C5 Age Estimation of Adolescents and Adults Using the Dimensions of the Eye and Pupil in “Selfie” Photographs

KariAnna Baber, BA, Marshall University Forensic Science Program, 1401 Forensic Science Drive, Huntington, WV 25701; Robert J. Boggs, West Virginia State Police Digital Forensics Unit, 1401 Forensic Science Drive, Huntington, WV 25701; Joshua L. Brunty, MS, Dept of Integrated Science & Technology, 1 John Marshall Drive, Huntington, WV 25755; Ian Levstein, MS, Marshall University, 1401 Forensic Science Drive, Huntington, WV 25701; and Terry Fenger, PhD, 1401 Forensic Science Drive, Huntington, WV 25701*

After attending this presentation, attendees will understand how to use dimensions of the eye and pupil to assess the age of an individual from a digital image.

This presentation will impact the forensic science community by demonstrating the effectiveness of investigating digital images and correlating an age with the photographed individual. This becomes most relevant for individuals in their teens, as they often appear older due to the use of makeup, posing, and filter technologies commonly used to take a picture of oneself, otherwise known as a “selfie.” By analyzing facial features, particularly the eye and pupil regions, the subject has less ability to hinder age estimation based solely on physical appearance.

Institution Review Board (IRB) approval was obtained in order to use human subjects. The reasoning of this project, as well as the safety and privacy of the participants, procedures, consent forms, and storage of data needed IRB approval. The target age group of participants is between 11-19 years old; however, participants not within the age range were accepted. Participants were recruited by word of mouth, personal connections, and e-mail communications. Those under the age of 18 years old were required to obtain parental permission and provide child assent. Those over the age of 18 years old required informed consent. Because there are many variables that influence the functionality of the pupils, such as mood, eye problems, medications, and lighting, images were taken under controlled conditions which include using the same room and lighting.

Each subject was given an Identification (ID) number for the project and asked a series of simple questions detailing his/her mood, medications, and eye-problem history as well as his/her age, birthday, and other demographic information. The illumination of the room was captured with a Dr. Meter® Digital lux meter for each participant, so that the camera settings and metadata from the Nikon® D3100 digital camera and Apple® iPad® iOS® Version 7.1.1 could be compared. Each participant sat 1.5 meters away from the digital camera and a set of two pictures were taken, one with a spontaneous gaze, looking past the camera, and the other with an attentive gaze, looking straight into the camera. A forensic evidence ruler was included in these photographs for accurate calibration of measurements using Adobe® Photoshop® CS5. Finally, the participant was asked to take a picture (a “selfie”) and a short video of him/herself using the iPad®. The distance at which the subject comfortably held the iPad® to perform these procedures was recorded.

The images were downloaded onto a computer for analysis using Photoshop®. Each image was calibrated so the pupillary diameter, area, and interpupillary distance could be determined and compared using formulas given in MacLachlan & Howland.¹ Using the known age of each participant and the age from the formulas, the effectiveness of age estimation can be determined.

C6 How Accurate is 3D Facial Morphology for Personal Identification?

*Petra Urbanová, PhD**, Kotlarska 2, Brno 611 37, CZECH REPUBLIC; *Igor Chalás, Masaryk University, Dept of Computer Graphics and Design, Faculty of Informatics, Brno, South Moravian Region 60300, CZECH REPUBLIC;* and *Barbora Kozlikova, PhD, Masaryk University, Botanická 554/68a, Brno 602 00, CZECH REPUBLIC*

After attending this presentation, attendees will be acquainted with the principles of computer-aided personal identification using 3D records of human faces, its technical and methodological imperfections, and novel modifications proposed to currently available algorithms.

This presentation will impact the forensic science community by providing insight into current state-of-the-art forensic facial identification and by introducing novel approaches designed specifically for forensic purposes, developed using the 3D Virtual Model Database of Human Faces.

The increasing accuracy of sensors used for capturing human faces together with advances in computer graphics and vision have had a great impact on the quality of images that are being admitted for forensic examinations. Matching image-based forensic evidence from crime scenes (surveillance videos) with suspects (mug shots, ID photographs) is known to be highly dependent on the image quality, optical distortion, perpetrator's head position, or disguise. Therefore, in many forensic cases, automatic computer-aided systems for facial recognition are of little use as they fail to provide positive (i.e., to identify a person), or negative (i.e., to eliminate a person) results. Currently, new development in 3D technologies has offered solutions to overcome these key limits by allowing 2D-to-3D and 3D-to-3D digital record matching.

Despite that fact that 3D video surveillance systems are being developed and are expected to be widespread in the near future, so far there has not been sufficient scientific evidence on how accurate and reliable it is to utilize 3D records of human faces for the purpose of forensic identification or whether matching 3D digital evidence meets legal requirements that demand the use of quantifiable scientific methods with known error rates. 3D human faces are generally captured by a variety of in-lab equipment — laser- or stereophotogrammetry-based devices, which eventually generate plain or textured photorealistic 3D meshes. Processing and matching two or multiple 3D surface meshes is a challenging task which requires a proper alignment algorithm together with appropriate numerical and visual representations. There are a number of existing algorithms and metrics, such as the Iterative Closest Point (ICP) for aligning two surface datasets or Hausdorff distances for quantifying actual distances between two aligned meshes. In addition, surface-based visualization technique is commonly performed using colormaps and scalar fields.

The present research tested the currently available algorithms for matching 3D faces using a dataset sampled from a large database of high-resolution 3D scans — the 3D Virtual Model Database of Human Faces. This study established a stripped version available throughout the project website; the database contains approximately 2,000 scans acquired for a variety of reasons — studies of individual and age-related human variation, growth and development studies, parent-to-offspring resemblance, etc. Specifically, it contains both subadult and adult individuals scanned repeatedly under controlled and semi-controlled conditions as well as those composing a large reference sample of non-matching individuals at a population level.

To improve the matching process, available algorithms were modified by introducing an iterative process of successive improvement of the average face speed up with KD-trees which allows a better alignment of 3D meshes when a multiple comparison is launched. The magnitude of dis/similarity among aligned meshes was expressed by signed and absolute Hausdorff distances (i.e., the greatest of all the distances from a vertex in reference mesh to the vertex in the compared one and further extended to incorporate vertex to polygon and inter-polygon distances).

The results show that all modifications to the tested algorithms proved to be useful for further development of a forensic 3D facial identification system; however, there are a number of other issues of computational and technical nature that need to be addressed in order to acquire high-match scores in same-person comparison. The purpose of this presentation is to present the issues to the forensic community.

C7 Effects of Latent Print Processing on Evidence Prior to Digital Evidence Examination

Charlotte W. Ware, MSFS, PO Box 3000, Charlotte, NC 28228; Angela R. Pratt, MFS, US Postal Inspection Service, National Forensic Laboratory, 22433 Randolph Drive, Dulles, VA 20104; and Anna R. Fridley, MFS, US Postal Inspection Service, National Forensic Laboratory, 22433 Randolph Drive, Dulles, VA 20104*

The goal of this presentation is to provide attendees with an understanding of the effect of latent print processing of evidentiary items that will subsequently undergo digital evidence examination.

This presentation will impact the forensic science community by providing information that will assist laboratories in determining the proper order of examination when evidence items are received that will undergo both latent print processing and digital evidence examination. If latent print processing is found to interfere with successful digital evidence examination, the digital examination will have to be performed prior to the latent print processing.

An increasing number of evidence items are being submitted to forensic laboratories in which both latent fingerprint examinations and digital evidence examinations are requested. During one of these recent submissions in the forensic laboratory, the question arose as to whether latent print processing should occur before the digital evidence examination in order to preserve any possible latent prints deposited on the evidentiary items or if the latent print processing would impede the ability to retrieve digital evidence from the items when they were examined subsequent to the processing. When items of digital evidence are examined, they are required to be powered on or energized in some way, utilizing the delicate electronic connections within the items. It is theorized that these delicate connections could be affected by the chemicals and process that are encountered when they are processed for latent prints, using cyanoacrylate fuming and subsequent dye staining processes.

In order to get a sampling consistent with the different types of items that could be submitted for digital evidence examination, the research included Universal Serial Bus (USB) flash memory drives of different sizes, media cards of different sizes, optical media including compact discs and Digital Video Discs (DVDs), and bare internal hard drives. Each evidence item contained data and a hash value was obtained for each item before any processing was performed. The items were then processed with cyanoacrylate fuming and subsequently a hash value was obtained for each item again. They were then processed with a dye staining process. After the dye stain, a hash value of each item was obtained again. The hash values of the item before any processing, after cyanoacrylate fuming, and after fuming and dye staining will be compared. The effects of the processing will be discussed, including the numbers of successful hash value comparisons that were able to be made at the conclusion of testing.

Digital Evidence Examination, Latent Print Processing, Evidence Processing Order

C8 Placing the Suspect “Behind the Keyboard” Through the Application of Handwriting Analysis to MS® Office OneNote® File Content

Thomas L. Murray, MS, US Army Criminal Investigation Laboratory, 4930 N 31st Street, Forest Park, GA 30297; and Joseph L. White, MS*, US Army Criminal Investigation Laboratory, Digital Evidence-CFI, 4930 N 31st Street, Forest Park, GA 30297*

After attending this presentation, attendees will have a general understanding of the potential value digitally captured handwritten content may provide in the individualization of digital evidence.

This presentation will impact the forensic science community by providing an additional method for linking an individual to specific digital evidence files and/or devices.

One of the common issues with the examination of Digital and Multimedia Evidence (DME) is individualization of reported data to a suspect. Without additional evidence such as fingerprints, photographic evidence, or witness testimony, placing the suspect “behind the keyboard” of an electronic device may be a daunting task for the DME examiner. This lack of ability to individualize the evidence to an individual, rather than just a “user of the electronic device,” is sometimes provided as an argument toward labeling DME examination as an investigative/intelligence tool rather than as a true forensic science. This presentation was developed from the results of an investigation where handwritten data allegedly captured using a tablet-type electronic device was individualized to the subject under investigation through handwriting comparison.

Evidence was submitted to the United States Army Criminal Investigation Laboratory (USACIL) for digital evidence analysis related to the possession of suspected child pornography. Of the 134 items submitted for analysis, 67 items were subjected to either a full or triaged analysis while the remainder were either non-functional, contained no data, or were remanded back to the submitting agency for either manual review or an additional request for further examination. Of the 67 items examined, 32 contained pictures and/or videos of interest to the investigation and seven items contained additional case-pertinent data. The results of the initial triaged analysis of the evidence indicated one of the largest collections of suspected child pornography in USACIL history.

In addition to the large amount of suspected child pornography, several Microsoft® (MS®) Office OneNote® files containing apparent handwritten content related to fantasized sexual relations with underage persons were observed. Coordination with the submitting agency resulted in a request to have a USACIL document examiner attempt handwriting comparison on the recovered digital data. A preliminary examination of the OneNote® files disclosed that the handwritten entries appeared to be freely and naturally written and contained sufficient detail for comparison. Copies of the files were provided to the submitting agency with instructions to obtain comparable known writing from the suspect. Upon receipt of the known writing samples, a handwriting examination comparing the questioned writing from the OneNote® files to the known writing of the suspect was conducted. The results of the examination identified the suspect as the author of the questioned handwritten entries.

As a result of the joint examination efforts between digital evidence and handwriting examiners, the suspect was conclusively linked to the electronic document and therefore linked to the device. With the development and enhancement of more electronic devices capable of capturing handwritten data such as tablets, touch-screen monitors, and smart phones, the likelihood of finding handwritten data on electronic devices may be increasing. The results of this case study indicate the potential for individualization of digital evidence through handwriting analysis conducted on digitally captured handwritten material. Therefore, these types of files should not be overlooked and a more concerted effort to look for these types of files may be warranted.

The opinions or assertions contained herein are private views of the author and are not to be construed as official or as reflecting the views of the Department of the Army or the Department of Defense.

Digital Evidence, Handwriting, Individualization

Digital & Multimedia Sciences Section - 2015

C9 The Role of Fantasy in Investigating Online Predation Cases

*Peter R. Stephenson, PhD**, 158 Harmon Drive, Rm 221B, Dewey Hall, Northfield, VT 05663; and *Richard D. Walter, MA*, 1879 Chenango Street, Montrose, PA 18801

After attending this presentation, attendees will be aware of ways to use close examination of internet communications to identify and investigate online predators. The presentation applies principles of hybrid crime assessment to identify pressure points at which the online predator is likely to become dissatisfied with cyberspace and seek to move his or her crimes into physical space. One tool for conducting these investigations is understanding the role of fantasy and how it can be manifested in relation to crimes in cyberspace.

This presentation will impact the forensic science community by providing a new investigative tool for conducting predator investigations that have both online and physical interactions between predators and their victims.

One online dictionary defines predation as, "...a relation between animals in which one organism captures and feeds on others"¹. In cyberspace online predation can have much the same definition; however, feeding on others usually becomes psychological rather than physical. Online predation almost always includes an element of fantasy, whether as a tool for exploitation or as a state of mind in the predator.

Contrary to some popular definitions, victims of online predators are not limited to children. Online predation is virtually always a power issue, often mixed with fantasy, and its targets depend upon the proclivities of the predator. Understanding this combination is useful as an investigative tool. Identifying the role of fantasy in the mind of the predator can assist the investigator in identifying and investigating the suspect.

Fantasy can take two forms. One way to differentiate is to view the fantasy as a way to escape into a world where day-to-day issues lose their importance. Healthy individuals fantasize periodically but generally emerge from their daydreams unscathed and, perhaps, refreshed; however, other individuals — not as mentally healthy — escape into fantasies and may not emerge. Their lives become integral with their fantasies and, at some point, those fantasies may evolve and develop to the point where the individual must act them out as part of his or her daily physical existence. Simply, these people lose the balance between the real world and their manufactured fantasy world. Consequently, they leave clues that can assist in investigating their activities and can also assist in tracing them through cyberspace and into physical space.

Cyberspace is an alternative dimension. It is a parallel universe that gives its denizens the ability to live in a world that meets their criteria and does not offer the normal disappointments of daily physical-world life. The presence of erotic chat rooms, sadomasochistic websites, and virtual worlds addressing other extremes of behavior attest to a market serving fantasies that are somewhat "off the grid." Online pornography has long been a topic for academic study, in part due to its breadth and depth. Deviant behavior is alive and well and has a home in cyberspace.

Humans live three lives: public, private, and secret. In the anonymity of cyberspace, it seems safe to acknowledge and act out the secret life. Investigators can use this behavior to predict physical behavior and, in some cases, predict the point at which it will emerge with dangerous consequences into physical space.

This presentation will explore two cases of online predation: a romance scam and a lengthy (over five years) international cyber stalking. Through examination of internet communications relating to these two cases, attendees will see examples of how online predators signal their unhealthy intentions and give clues about how to locate and investigate them. Both of the predators lived in worlds of fantasy and in both cases their behavior online signaled emergent behavior in physical space. In one case, investigators were successful in bringing the perpetrator to justice while in the other case, the suspect is still at large.

The presentation will discuss the issues involved in fantasy, the two exemplar cases, and, finally, the evidence available to digital investigators following the suspects in cyberspace.

Online Predator, Digital Investigation, Fantasy

C10 3D Superimposition: A New Technique of Personal Identification

Antonio De Donno, PhD, P.zza Giulio Cesare n.11, Bari 70124, ITALY; Sergio Lubelli, PhD, D.I.M., Sezione di Medicina Legale, piazza Giulio Cesare, 11, Bari 70124, ITALY; Valeria Santoro, PhD, P.zza Giulio Cesare n.11, Bari 70124, ITALY; Fulvio Lavecchia, PhD, Politecnico di Bari, Dipartimento di Ingegneria Meccanica e Gestionale, v.le Japigia 182, Bari 70126, ITALY; Luigi M. Galantucci, PhD, Politecnico di Bari, Dipartimento di Ingegneria Meccanica e Gestionale, v.le Japigia 182, Bari 70126, ITALY; and Francesco Introna, MD, Dim Sezione Di Medicina Legale, P.zza Giulio Cesare 11, Bari 70124, ITALY*

After attending this presentation, attendees will be informed about a new technique of personal identification.

This presentation will impact the forensic science community by presenting a standardized technique for personal identification based on 3D superimposition.

The goal of this presentation is to show an objective, non-invasive, technique for the subject's personal identification through an analysis of recorded images and 3D avatar superimposition.

Personal identification based on 3D digital stereophotogrammetry presents a natural evolution of previous research in this field, the so-called "Parameterized Superimposition (PS)." Total cooperation of the suspect and the structure where the offense was perpetrated are boundaries of the PS technique. Photogrammetry currently provides the most cost-effective 3D capturing system as it is quick, inexpensive, and non-invasive; the equipment necessary for acquisition is easily transportable and offers high reliability. The technique was suitable for capturing facial morphology for clinical and anthropological usage. This technique involved four steps:

Preparatory Phase: The recorder images of a subject were studied and improved. Frames with a better view of the subject's facial landmarks were then chosen.

3D Acquisition Phase: A 3D stereophotogrammetric avatar of the subject's face was created; this phase only required four photos taken simultaneously with a calibrated camera.

Superimposition Phase: This phase was the preparatory phase for the final step. The 3D avatar of the subject's face was carefully spatially oriented in the same position as in the photos and snapshots that were previously taken. During the morphological analysis, the snapshot of the 3D avatar was superimposed on the frame of the subject's picture by a specific software.

Metric Image Analysis: To perform this step, it was necessary to clearly recognize at least five landmarks on the 3D avatar using appropriate software. A 3D parameterized avatar of the subject was created with a stereophotogrammetric technique and the subject's frame was selected and acquired. In the metric image analysis step, a quantitative comparison between the image of the frame of subject's face and the avatar's snapshot was obtained. Objective anthropometric landmarks, such as exocanthions, glabella, and asubspinal point, were marked on the 3D avatar and on the picture of the frame of the subject's face to calculate the distance of the absolute points discerned on those two images.

Results: The absolute and relative distance between the marked points, the perimeters, and the area of the triangles, obtained by connecting the points, and the compactness indices were automatically calculated with a proper program.

Conclusion: The morphologic phase revealed a full overlap between the 3D avatar and the frame's picture. Metric phase revealed that correlation coefficient values, higher than .998, confirm the identification hypothesis. The technique described is objective, repeatable, and not invasive. Technical skills are required, meaning that improvisation is not allowed.

Personal Identification, 3D Superimposition, Anthropology

Digital & Multimedia Sciences Section - 2015

C11 Online Anonymity: Forensic Analysis of The Onion Router (Tor) Browser Bundle

Darcie Lynn Winkler, BS, 1106 11th Avenue, Apt 4, Huntington, WV 25701; Robert J. Boggs, West Virginia State Police Digital Forensics Unit, 1401 Forensic Science Drive, Huntington, WV 25701; John E. Sammons, MS, 18 Quail Drive, Ona, WV 25545; and Terry Fenger, PhD, 1401 Forensic Science Drive, Huntington, WV 25701*

After attending this presentation, attendees will understand the manner in which The Onion Router (Tor) provides anonymity to its users, some of the vulnerabilities that exist within the software, and a few forensic analysis techniques that are capable of circumventing the secrecy.

This presentation will impact the forensic science community by allowing practicing digital forensic analysts to take away valuable information pertaining to the Tor Browser Bundle (TBB) that may save time in future investigations as attendees will be aware of several methods that will and will not work in the process of gathering pertinent evidence.

Tor is a network of encrypted onion routers that helps to increase the level of anonymity experienced by its users. The security and privacy provided by the TBB was originally intended to protect the communications of the government; however, it is also a facilitator for individuals participating in illicit activities. It was hypothesized that if correct methodology is executed and the data collected is analyzed using pre-existing forensic techniques, then relevant evidence of the browsing history and presence of the TBB may be acquired. To test this, Virtual Machines (VM) were constructed to test four possible scenarios: (1) a machine running only Internet Explorer®; (2) a machine with TBB downloaded but no active use recorded; (3) a machine with TBB downloaded and used to navigate both the internet and Darknet; and, (4) a machine where TBB had been installed, used, then uninstalled. Furthermore, an additional VM was created solely for the purpose of tracking registry changes throughout the course of installing and uninstalling the TBB. It is hoped that beneficial information will become evident by capturing packets while the TBB is navigating to .onion and .com websites, dumping the Random Access Memory (RAM), and comparing versions of the registry from various points of the installation process.

In conclusion, the RAM dump provided several file types from the carved image that linked the web browsing to the TBB and several .onion sites. The registry files demonstrated that deleting Tor does not carry out a full uninstallation, thereby leaving artifacts behind. Lastly, the packet capture proved that Tor traffic is very different in appearance and content than that of a standard web browser.

Each method employed reaped beneficial artifacts proving that the TBB does not provide complete anonymity. These techniques would for the most part only be applicable in a proactive network forensics environment using a remote process to monitor a suspect's activity. Therefore, it is less likely that these methods would be used in a digital forensics lab that receives evidence from a crime scene. Naturally, the digital forensic community will remain persistent in their quest to refine an applicable technique that will adequately gather incriminating evidence from a hard drive subsequent to collection; however, without more advanced technology and abundant resources like those available to government agencies such as the Federal Bureau of Investigation (FBI) and the National Security Agency (NSA), digital analysts will be hard pressed to find a reliable method of breaking through the anonymity provided by the TBB for confiscated hard drives and associated digital evidence.

Anonymity, Forensic Analysis, Tor Browser

C12 Fingerprint Replication Utilizing Latent Fingerprints for Conducting Forensic Analysis on Mobile Devices With Biometric Security

*Joshua D. Sablatura**, SHSU Digital Forensics, 2537 Pine Shadows Drive, Apt 434D, Huntsville, TX 77320; *Robert McDown, BS**, Sam Houston State University, 1803 Avenue I, Huntsville, TX 77341; *Jorn Chi-Chung Yu, PhD*, Sam Houston State University, Dept of Forensic Science, Box 2525, Huntsville, TX 77341; and *Lei Chen, PhD*, Sam Houston State University, 1803 Avenue I, Huntsville, TX 77341

After attending this presentation, attendees will have a better understanding of biometric security, specifically fingerprint recognition, in personal digital devices, a technical understanding of the device's specific operations, and of the means for circumventing the device's biometric security to conduct a digital forensics analysis.

This presentation will impact the forensic science community by providing a supplemental means to collect digital evidence from personal devices that are protected with biometric security systems. Current techniques for data extraction on mobile devices include brute forcing pin codes, software security bypass via custom boot-loader, and physical data extraction using a Joint Test Action Group (JTAG) connection; however, these methods are not always implementable under the following conditions: (1) the device allows a limited number of pin code entries before the device locks itself or wipes the data; (2) the operating system does not have a known security bypass; or, (3) the data on the device is encrypted rendering a physical data extraction useless.

The goal of this project is to develop techniques to visualize a latent print from the surface of a mobile device; this print can then be used to develop a mold that can reconstruct the user's print. After using fingerprint powders to lift a print from the device surface, a digital image of the print was created using either a scanner or camera. This image was imported into an image processing software package in order to use the color range selection tool to extract the print from the background. The threshold tool was then used to enhance the print's clarity from the background while converting the image to black and white.

After creating a viable image, a mold was created using either the Printed Circuit Board (PCB) or 3D printing method. Of these two methods, the PCB method is the low-tech, low-cost method to create the mold. This method involves printing the enhanced image with a laser-jet printer to a transfer medium. Using a heat source, the image is transferred from the transfer medium to a copper-clad board. Once the image has been transferred, ferric chloride is used to etch the excess copper from the board, leaving behind the copper concealed by the image transfer. The 3D printing method is more expensive due to the materials and equipment utilized. After the enhanced image is obtained, it must be extruded into a 3D image using a Computer-Aided Design (CAD) program. This is then printed with a 3D printer to create the mold. Using the mold created from either method, the fingerprint can then be reconstructed with a material that mimics the conductivity and pliability of human skin.

This study indicates that the use of gelatin, ballistics gel, and Elmer's® white glue are viable candidates that can be used in the process of reconstructing the fingerprint as each of these substances is recognized by the device's scanner. Currently, research is in progress to refine the methods used to create the molds and to enhance the extracted fingerprint image to produce a more accurate reproduction. This provides additional evidence, not present in the digital examination, but likely to be very useful in an investigation that includes mobile devices.

Biometric Security, Digital Forensics, Fingerprint Reconstruction

C13 Implications for Digital Forensics Investigations of the United States 2nd Circuit Ruling Upholding Deletion of Non-Responsive Computer Files: A United States and European Union/Germany Perspective

Donald J. Horowitz, JD, c/o 4311 11th Avenue, N, Seattle, WA 98105; Barbara E. Endicott-Popovsky, PhD, 4311 11th Avenue, NE, Ste 400, Seattle, WA 98105; Aaron Alva, 2001 E Yesler Way, #33, Seattle, WA 98122; Hellen Schiling, PhD, Kempf & Dannenfeldt, Siesmayerstraße 58, Frankfurt am Main 60323, GERMANY; Carsten Rudolph, PhD, Fraunhofer SIT, Institute for Secure Information, Technology, Darmstadt, GERMANY; and Nicolai Kuntze, Rheinstrasse 75, Darmstadt, Hessen 64295, GERMANY*

The goals of this presentation are to discuss ruling impacts and to describe current research in the United States and the European Union/Germany addressing selective suppression.

After attending this presentation, attendees will better understand the results of research into technical and legal issues arising from this landmark decision. This has significant technical and legal implications for all digital forensics investigations.

In *United States v. Ganas*, June 2014, the Second Circuit held that the government has a duty to delete or return non-responsive data it had previously seized through a valid search warrant, raising the bar for what the government must do post-seizure of digital evidence.¹ Attendees will learn the results of this research into technical and legal issues arising from this landmark decision. This has significant technical and legal implications for all digital forensics investigations.

This presentation explores the implications of this ruling from the technical and legal perspectives of experts in the United States and the European Union and of members of a digital forensics research collaboration between the University of Washington and Fraunhofer Institute Darmstadt. This study also discusses comparative selective suppression procedures used in Germany.²⁻⁵

Technology and policy are often on a collision course; this ruling is an example. The technical challenges are many: (1) how do we delete non-responsive data from disk images without violating the integrity of responsive files; (2) what do we do with hash values and digital signatures; (3) how do we edit video and audio files to show that all retained parts correspond to their respective parts from the original file; (4) how do we create signatures that show which parts were deleted; and, (5) how do we delete parts of a database without violating relevant data or complete databases with mainly non-responsive information that might not be retained at all?

Additional legal/policy concerns include: (1) what procedures will the government use to delete non-responsive data; (2) whose responsibility will it be to perform the deletion; (3) must the government verify the deletion and, if so, how can the deletion be verified; (4) how long can a non-responsive file be retained before it becomes an unreasonable seizure; (5) how does this interact with rights that criminal defendants have on appeal; (6) what is considered a “document;” and, (7) who decides what is non-responsive?

Although the government argued that selective deletion from an imaged hard drive would be impractical, the court stated that it was not entirely convinced: “But even if we assumed it were necessary to maintain a complete copy of the hard drive solely to authenticate evidence responsive to the original warrant, that does not provide a basis for using the mirror image for any other purpose.” This begins to imply what the court thinks authenticity may entail, but raises the additional questions described above.

Similar to the United States, in Germany, infringement due to search-and-seizure measures is justified only on the condition that they are in accordance with the German Criminal Procedure Code, securing data always requires the object in question to be of significance for the investigation.⁶ To determine evidentiary significance, off-site reviews are permitted pursuant to the German Criminal Procedure Code.⁷ As soon as a decision is made, these documents/data must be returned or deleted; however, German authorities recognize that selective suppression was “impractical,” respectively “technically impossible,” due to harming the validity of a mirror image.¹

In contrast, securing storage media in Germany is enshrined in the constitutionally guaranteed “right on informational self-determination” and the “guarantee of the confidentiality and integrity of IT-systems”; both rights derive from the general “right of freedom” in connection with the “guarantee of human dignity” of the German Basic Law.^{8,9}

This study explores the technical and legal research on selective suppression. While the technical team explored a technical solution to the questions raised in this presentation, it was discovered that German procedures for off-site review and their views on rights regarding digital information have relevance to questions raised by the 2nd Circuit decision.¹ These will be discussed and reviewed anticipating that the discoveries and insights in this study may be helpful to those adapting their digital forensics investigations to updated decisions.

C14 Modeling Digital Autopsies on Medical Autopsies

Martin S. Olivier, PhD*, University of Pretoria, Computer Science, Pretoria 0002, SOUTH AFRICA

After attending this presentation, attendees will be able to reflect on tests for “normality” during digital forensic examinations to exclude possible alternative explanations that may fit the facts in a case.

This presentation will impact the forensic science community by increasing reliability of findings in certain cases.

Forensic examination is at the core of digital forensics practice. Examination uses science to provide an answer to a question that is relevant for legal or related purposes. The question may entail association, event reconstruction, or some other insight from forensic evidence. Once an answer x is obtained, the question can be reformulated in the form: Is x true? The outcome of such an examination then is a (qualified) *yes* or *no* (or *unable to determine*). The need to qualify the *yes* or *no* relates to the level of certainty with which the question can be answered.

Digital forensics certainty (or error rate) remains problematic.^{1,2} The premise of this presentation is that certainty is increased when alternative explanations have been eliminated. Digital forensic examination research often focuses on specific technologies that are subject to change — reducing certainty. This study suggests that more technology-neutral research needs to be done as a precondition for expressing confidence.

Unifying forensic science may be unrealistic, but metaphors from the medical sciences are common in digital forensics (e.g., the notion of a dead examination or the Autopsy Forensics Platform).³ Conducting a thought experiment to explore a mapping between medical autopsies and digital forensic autopsies is therefore prudent.

The first striking similarity considered in this presentation is the crisis experienced in medicolegal death investigations in the 1800s due to the variety of (questionable) methods used. Rudolf Virchow is credited with establishing a method to conduct autopsies that met scientific standards and that subsequently became the standard protocol.⁴ Arguments about the “scientificness” of digital forensics continue and are raised in the presentation.

One of the characteristics of the Virchow protocol is that the entire body is examined irrespective of the presumed cause of death. It avoids confirmation bias. The study demonstrates the general acceptance of this (unintuitive) imperative. The internal examination consists of a systematic removal of the organs; each organ is inspected to establish its consistency with expected (“normal”) characteristics. Similar verification is a significant difference between autopsies in these disciplines. Another significant difference is the nature of findings. These differences and the validity of transferring imperatives from one discipline to the other are considered in the study.

Is it possible (and meaningful) to “remove organs” from digital artifacts and express an opinion on the normality of such “organs”? The digital equivalent of an organ is a system, subsystem, or an application (henceforth, system). The National Institute of Standards and Technology (NIST) National Software Reference Library already catalogs hashes of files occurring “normally” in many systems. This experiment requires more: it needs a version of a system consisting of a number of “known” files. A database with at least two sets per system is required — a set of file hashes for a minimal installation as well as a similar set for a full installation of a system. Details and relevant logic of which files should be included forms part of the presentation. In such a database, for any system S_i , the set of hashes corresponding to a full install will be denoted by $\uparrow S_i$ and $\downarrow S_i$ will be used for the minimal case. Assume that F is the set of hashes of all found files. Then $FS_i = \{f \in F \mid f \in \uparrow S_i\}$ is a potential system (or “organ”); if $\downarrow S_i \subseteq FS_i$ then FS_i may be considered “normal.” It also means that every $f \in FS_i$ has been accounted for. Shared files need special consideration. This presentation will argue that “normality” of files not included in the hash sets implies syntactic correctness. Additional criteria for some excluded categories apply.

The proposed approach verifies “normality” of system anatomy beyond the primary focus of the examination. This may be extended to physiological “normality” — where cause and effect, and, hence, valuable evidence may be revealed.

This presentation includes some observations about practical difficulties in identifying the “organs” from a small proof-of-concept experiment.

C15 Exploring Myths in Digital Forensics

Gary C. Kessler, PhD*, Embry-Riddle Aeronautical University, 600 S Clyde Morris Boulevard, COAS 128.06, Daytona Beach, FL 32114; and Gregory H. Carlton, PhD, Cal Poly Pomona, Computer Information Systems Dept, 3801 W Temple Avenue, Pomona, CA 91768

The goals of this presentation are to explain the evolution of digital forensics as a practice and to explore the historical rationale of some of the “myths” leading to the “best practices” in digital forensics and why many may no longer be relevant given today’s technologies.

After attending this presentation, attendees will have a better perspective of applying admissibility tests to digital evidence.

Digital forensics — née *computer forensics* — is one of the newer forensic science sections in the American Academy of Forensic Sciences (AAFS), having been established in 2008. After attending this presentation, attendees will understand some of the fundamental differences between digital forensics and the more traditional forensic sciences. Among these differences is the historical way in which digital forensics has evolved as a science and a field of practice. Appreciation of these differences may contribute to the conversation surrounding the current work of the National Institute of Justice and the National Institute of Standards and Technology as they try to codify a definition of the science of digital forensics.

Unlike the traditional forensic sciences, digital forensics investigations and methodologies were originally developed 30 years ago by computer-savvy users and practitioners rather than by the computer science community. The development of computer forensics as a discipline and field of study was very ad hoc in the 1980s and 1990s; indeed, there were very few computer forensics examiners who were not in the law enforcement community during that era. Furthermore, computer forensics courses and curricula in higher education were practically non-existent 15 years ago.

The acceleration of change in computer technology over the last 25 years has resulted not only in changing digital forensics hardware and software tools and methodologies, but also in big changes in the very technology that holds the evidence, ranging from floppy disks and hard drives to smartphones and solid-state memory devices. Many of the “best practices” of the 1990s are actually irrelevant with today’s technologies, yet are still taught in training and education programs today. Decisions based upon the adherence to the myths might cause investigators or prosecutors to not introduce probative evidence at trial, falsely believing that such evidence would not withstand a challenge in court; alternatively, a challenge might be successfully mounted due to a lack of understanding of true best practices.

This study will introduce several of the long-held computer forensics myths and discuss their place in the modern practice of digital forensic science.

Digital Forensics, Best Practices, Evidence

Digital & Multimedia Sciences Section - 2015

C16 Forensic Investigation of Crimes Committed by Unmanned Systems

Victor W. Weedn, MD, JD*, George Washington University, 2100 Foxhall Road, NW, Somers Hall, Lower Level, L-12, Washington, DC 20007; and Anthony M. Hallett, Unmanned Response, Inc, 119B Lion Lane, Beaver, PA 15009

After attending this presentation, attendees will appreciate the potential of unmanned systems for the perpetration of crimes and will appreciate the problems they pose for forensic investigations.

This presentation will impact the forensic science community by introducing the threat posed by the use of unmanned systems, to include robots and drones, to commit crimes and the lack of preparedness by the forensic community to address it.

After centuries of mythology and conceptualization, robots are suddenly among us and they are rapidly proliferating. They can walk, swim, and fly. They are inexpensive and easy to operate. As with all machines, they are, at least for now, extensions of their human controllers.

As with any technology, today's robots, commonly referred to as drones, will be embraced by voyeurs, stalkers, child molesters, blackmailers, criminals, smugglers, and terrorists. Drone-assisted crimes have already surfaced: a plan for a model airplane carrying explosives to the Pentagon was thwarted, a quad-copter carrying contraband was detected scaling a prison wall, and a submarine carrying drugs to shore was captured; however, it is likely that many similar crimes have gone undetected.

There is every reason to believe that forensic investigators will soon be asked to conduct examinations of drones that were involved with significant accidents or crimes. Investigation of such cases, where the human perpetrator was *in absentia*, pose daunting challenges that will require special methodologies.

How will such an examination proceed? Unless the robot or drone is captured or found, there will be no fingerprints or biologic stains at the scene. Instead of footprints, there may be some sort of tread marks or, in the case of an aerial drone, perhaps no markings at all. Evidentiary procedures and even longstanding investigation paradigms (such as placing the perpetrator at the scene of the crime) are disrupted by drones. A digital examination of the drone may yield some important data. Perhaps a digital trail had been left on nearby cell phone towers. The drone may have a photo or video camera on board that may yield valuable data, but so might an examination of its mechanical systems or a chemical analysis of Chemical, Biological, Radiological, and Nuclear (CBRN) trace evidence. Even the "behavior" of the drone might reveal clues about its operator.

One can think of drone-assisted aggression as cybercrime that transcends beyond the limitations of the digital spectrum: it deploys a physical platform that can move, act, and react. An analogy can also be made to traditional murder-for-hire crimes, where another human is used as a *tool* to perpetrate the crime — only here, a machine is contemplated instead of a person. Analysis of cases involving human surrogates may provide insights for forensic investigators.

Sales of aerial drones account for approximately 80% of the unmanned systems market and nearly all of the media attention. The focus of drone manufacturers is transitioning from military to domestic markets as the Federal Aviation Administration readies the skies for commercial drone traffic (likely to be widespread by 2016), which they believe will reach 15,000 units by 2020. Sales to hobbyists, who can currently fly drones that weigh under 55 pounds, are reaching thousands of units per month.

With the dramatic increase in domestic drone use, it is reasonable to assume a corresponding rise in drone misuse (accidents) and abuse (crimes), many of which will be embedded in criminal and civil investigations and court cases. Yet, despite the enormous implications for the forensic science community, no references to presentations or papers written on this subject by forensic scientists have been found. Thus, it is a reasonable conclusion that the forensic community is ill-prepared to deal with the many threats presented by drones. Possible approaches to investigation of these crimes will be discussed.

Drones, Robots, Unmanned Systems

Digital & Multimedia Sciences Section - 2015

C17 Cloud Computing Forensic Science Challenges

Josiah Dykstra, PhD, Department of Defense, 8080 Greenmead Drive, College Park, MD 20740; Lon Gowen, PhD, United States Agency for International Development, 2733 Crystal Drive, Ste 11-510, Two Potomac Yard, Arlington, VA 22202; Martin Herman, PhD, 100 Bureau Drive, Mail Stop 2000, Gaithersburg, MD 20899; Michaela Iorga, PhD, National Institute of Standards and Technology, Information Technology Laboratory, 100 Bureau Drive, Gaithersburg, MD 20899; Robert Jackson, MS, SphereCom Enterprises Inc, 7900 Sudley Road, Ste 416, Manassas, VA 20109; Otto Scot Reemelin, MS, CBIZ, Inc, 3101 N Central Avenue, Ste 300, Phoenix, AZ 85012; Ernesto F. Rojas, MBA, PO Box 597, Seabrook, TX 77586; Keyun Ruan, PhD, Espion Group, Corrig Court, Corrig Road, Sandford Industrial Estate, Dublin 18, Dublin, IRELAND; A. Michael Salim, MS, American Data Technology, Inc, PO Box 12892, Research Triangle Park, NC 27709; Ken E. Stavinoha, PhD, Cisco Systems, 170 W Tasman Drive, San Jose, CA 95134; Laura P. Taylor, MS, Relevant Technologies, 10440 Little Patuxent Parkway, Ste 900, Columbia, MD 21044; and Kenneth R. Zatyko, MS, Ernst & Young LLP, 1101 New York Avenue, NW, Washington, DC 20005*

After attending this presentation, attendees will have a better understanding of some of the main challenges faced by forensic investigators attempting to identify, collect, analyze, and interpret digital evidence residing in cloud computing environments.

This presentation will impact the forensic science community by describing research performed by the National Institute of Standards and Technology (NIST) Cloud Computing Forensic Science Working Group, which was established to aggregate forensic science challenges in the cloud environment and to develop plans for measurements, standards, and technology research to mitigate the challenges that cannot be handled with current technology and methods.

The cloud exacerbates many technological, organizational, and legal challenges already faced by digital forensics examiners. Several of these challenges, such as those associated with data replication, location transparency, and multi-tenancy, are somewhat unique to cloud computing forensics.

The Group plans to prioritize the challenges enumerated. For high-priority challenges, gaps in technology and standards will be determined, resulting in a roadmap for addressing the challenges.

The challenges this study has aggregated are categorized into the following groups:

Architecture (e.g., diversity, complexity, provenance, multi-tenancy, data segregation, etc.) — Architecture challenges in cloud forensics include dealing with variability in cloud architectures between providers; tenant data compartmentalization and isolation during resource provisioning; proliferation of systems, locations, and endpoints that can store data; accurate and secure provenance for maintaining and preserving chain of custody; infrastructure to support seizure of cloud resources without disrupting other tenants; etc.

Data Collection (e.g., data integrity, data recovery, data location, imaging, etc.) — Data collection challenges in cloud forensics include locating forensic artifacts in large, distributed, dynamic systems; locating and collecting volatile data; data collection from virtual machines; data integrity in multi-tenant environments where data is shared among multiple computers in multiple locations and accessible by multiple parties; inability to image all the forensic artifacts in the cloud; accessing data of one tenant without breaching the confidentiality of other tenants; recovery of deleted data in a shared and distributed virtual environment; etc.

Analysis (e.g., correlation, reconstruction, time synchronization, logs, metadata, timelines, etc.) — Analysis challenges in cloud forensics include correlation of forensic artifacts across and within cloud providers; reconstruction of events from virtual images or storage; integrity of metadata; timeline analysis of log data including synchronization of timestamps; etc.

Anti-Forensics (e.g., obfuscation, data hiding, malware, etc.) — Anti-forensics are techniques used specifically to prevent or mislead forensic analysis. Challenges in cloud forensics include the use of obfuscation, malware, data hiding, or other techniques to compromise the integrity of evidence; malware may circumvent virtual machine isolation methods; etc.

Incident First Responders (e.g., trustworthiness of cloud providers, response time, reconstruction, etc.) — Incident first-responder challenges in cloud forensics include confidence, competence, and trustworthiness of cloud providers to act as first responders and perform data collection; difficulty in performing initial triage; processing a large volume of forensic artifacts collected; etc.

Role Management (e.g., data owners, identity management, users, access control, etc.) — Role management challenges in cloud forensics include uniquely identifying the owner of an account; decoupling between cloud user credentials and physical users; ease of anonymity and creating fictitious identities online; determining exact ownership of data; authentication and access control; etc.

Digital & Multimedia Sciences Section - 2015

Legal (e.g., jurisdictions, laws, service level agreements, contracts, subpoenas, international cooperation, privacy, ethics, etc.) — Legal challenges in cloud forensics include identifying and addressing issues of jurisdictions for legal access to data; lack of effective channels for international communication and cooperation during investigations; data acquisition that relies on the cooperation of cloud providers, as well as their competence and trustworthiness; missing terms in contracts and service level agreements; issuing subpoenas without knowledge of the physical location of data; seizure and confiscation of cloud resources may interrupt business continuity of other tenants; etc.

Standards (e.g., Standard Operating Procedures (SOPs), inter-operability, testing, validation, etc.) — Standards challenges in cloud forensics include lack of even minimum/basic SOPs, practices, and tools; lack of inter-operability among cloud providers; lack of test and validation procedures; etc.

Training (e.g., forensic investigators, cloud providers, qualification, certification, etc.) — Training challenges in cloud forensics include misuse of digital forensic training materials that are not applicable to cloud forensics; lack of cloud forensic training and expertise for both investigators and instructors; limited knowledge by record-keeping personnel in cloud providers about evidence; etc.

Digital Forensics, Cloud Computing, Forensics Challenges

Digital & Multimedia Sciences Section - 2015

C18 Federated Testing: Shared Test Materials From the Computer Forensics Tool Testing (CFTT) Program at NIST for Digital Forensics Tool Validation and Shared Test Reports

Benjamin R. Livelsberger, MS, 100 Bureau Drive, Mail Stop 8970, Gaithersburg, MD 20899-8970; Richard Ayers, MS, 100 Bureau Drive, Mail Stop 8970, Gaithersburg, MD 20899-8970; and Barbara Guttman, BA, National Institute of Standards & Technology, Mail Stop 8970, Gaithersburg, MD 20899-8970*

After attending this presentation, attendees will be familiar with the Federated Testing materials being developed by Computer Forensics Tool Testing (CFTT), understand how they can be used in their labs to timely and effectively validate tools, and learn how the Federated Testing initiative encourages shared tool validation results. Federated Testing at the National Institute of Standards and Technology (NIST) is an expansion of the CFTT Program that provides digital forensics labs and practitioners with test materials for tool validation.

This presentation will impact the forensic science community by providing information as to how the NIST Federated Testing materials can be used in digital forensics labs for tool validation at a savings of time and expense and how the Federated Testing materials support shared tool validation results.

Forensic tools need to be validated before being used in the forensic process. These tools need to be validated: (1) to ensure that digital evidence is being correctly processed; and, (2) to support the admissibility of digital evidence in court and legal proceedings. Tool validation is difficult, expensive, and time consuming.

The various federal, state, and local digital forensics laboratories use the same tools or the same types of tools. It follows that a lot of work is duplicated in tool validation. The CFTT program currently creates tool specifications, test methods, and test reports. The goal and purpose of Federated Testing is to simplify, package, and export the CFTT test methodologies and the expertise used to produce the NIST test reports to laboratories and individual examiners for use in tool validation.

The Federated Testing initiative offers several anticipated benefits to laboratories and examiners. A primary benefit is one of time and cost savings. If laboratories can use the NIST methodology and materials for tool validation, they save the time otherwise spent to develop their own. Federated Testing can also improve the quality of testing. CFTT's shared test materials additionally present a new opportunity for shared tool validation reports. A current barrier for laboratories for sharing tool validation results is that each laboratory will test a tool differently. A further barrier is dissimilar formats between laboratories for documenting and presenting tool validation results. This makes it difficult for a laboratory to understand how an externally validated tool was tested and to determine if the tests and validation results are acceptable for use in their own laboratory.

When tools are validated using the CFTT shared test materials, a common methodology is used and the results are reported in a common format. This makes it easy for a laboratory receiving a shared validation report to quickly understand how a tool was tested and to determine whether the validation results are acceptable and applicable for use in their own laboratory. Tool validation results from CFTT's Federated Testing shared test materials can be shared informally between laboratories, could be submitted to and shared via public websites such as the Department of Homeland Security Science and Technology (DHS S&T) -sponsored cyberfetch.org or CFTT's Computer Forensics Tool Catalog, or be kept private within the tester's organization.

Federated Testing is a work in progress. CFTT currently has test methodologies for disk imaging, forensic media preparation, hardware write blocking, deleted file recovery, mobile device acquisition and analysis, and file carving. CFTT is first implementing Federated Testing for disk imaging; test materials for the other functionalities will follow.

The test materials are being packaged on a live Linux® Digital Video Disc (DVD). The materials consist of the DVD, which contains video tutorials on how to use the materials, a website, and command line test support tools. Using the website, users select the type of tool they wish to test (e.g., disk imaging tool), then select the specific features they wish to validate. This results in a list of the tests to run in order to test these features, along with the steps and instructions for each test. The test instructions reference CFTT's test support tools. Run from the command line on the DVD, the support tools are used to set up each test and to analyze the results. When all the tests have been run, the website generates the tool validation results in the CFTT Federated Testing common report format.

Digital Forensics, Tool Validation, Federated Testing

C19 Implications of Valid Data Length (VDL) Slack and the Facts That It Presents

David G. Ferguson, MS, Deloitte, 1919 N Lynn Street, Arlington, VA 22102-4219*

After attending this presentation, attendees will be familiar with Valid Data Length (VDL) slack and its implications for forensic examinations. Examiners will learn what VDL slack is, how to detect it, and how to handle the two distinct hashes that these files have.

This presentation will impact the forensic science community by bringing awareness to the fact that VDL slack is not widely known by examiners, few have run into it, and it is rarely taught in examiner training. VDL slack has a number of interesting properties, one of which is that it has two distinct hashes.

Many examiners are unfamiliar with VDL slack and its potential impact on their reports or potential testimony. This presentation introduces the topics and presents some interesting facts that can be derived from files with VDL slack. After attending this presentation, attendees will understand some of the unique characteristics of files that contain VDL slack (sometimes called file tail), how to detect these files, how they are created, and what they can mean to forensic examiners. One of the unique characteristics is that files that contain VDL slack have potentially two different hashes. In addition, copies of files with VDL slack can be traced back to an original file with certainty (this could be useful in child pornography distribution cases).

VDL slack is an artifact of the Microsoft's® object reuse strategy for disk space. When Microsoft® introduced New Technology (NT) and the New Technology File System (NTFS) in the 90s, they wanted to get a C2 security rating from the National Security Agency (NSA). This required that, when disk space was reused, the new user could not be allowed to see what was there before. To allow efficient reuse, Microsoft® added the VDL value in the Master File Table (MFT) entry for each file. The VDL value is in addition to the file length in the MFT as they are separate and distinct values in the MFT. When a file is created by Windows®, if the file size is known, the file is created with the file length equal to the size provided by Windows® and the VDL is set to zero. So, the VDL is always smaller or equal to the file length. As data is written to the new file, the VDL is increased to include the new data. In practice, the VDL value in the MFT is almost always the same as the file length value. When the two values are not the same, the file contains VDL slack.

VDL slack has been around for years, but it is relatively rare and only occurs on NTFS partitions. A survey of more than 10,000 partitions found that 50% of the drives had at least one file with VDL slack and on average there were ten files with VDL slack per partitions. Most of the time, the files with VDL slack are relatively large (over 1GB).

So why should an examiner learn about VDL slack? For a forensic examiner, a working knowledge of VDL slack, at a minimum, can be useful in limited cases. In some cases, a file containing VDL slack could contain data that is crucial to the case. An examiner that is ignorant of VDL slack runs the risk of appearing to be confused on the witness stand or confusing a VDL slack for an intentional attempt at hiding data. In either case, their testimony could be lacking in true understanding.

VDL, Valid Data Length, NTFS

Digital & Multimedia Sciences Section - 2015

C20 Steganography Analysis: Efficacy and Response Time of Current Steganalysis Software

Jordan B. Green, BS, Marshall University, 317 Gallaher Street, Huntington, WV 25705; Ian Levstein, MS, Marshall University, 1401 Forensic Science Drive, Huntington, WV 25701; Robert J. Boggs, West Virginia State Police Digital Forensics Unit, 1401 Forensic Science Drive, Huntington, WV 25701; and Terry Fenger, PhD, 1401 Forensic Science Drive, Huntington, WV 25701*

After attending this presentation, attendees will understand the basics of steganography including methods of hiding information, applications, practical use, and the current software used to analyze hidden data.

This presentation will impact the forensic science community by educating digital forensic investigators about a form of data obfuscation that is difficult to detect in a practical setting. Awareness of its presence, especially in the realm of organized crime and terrorism, is a first step in addressing the proliferation of potentially illicit data.

Steganography, Latin for “covered writing,” is a method of hiding information within digital media. In steganography, a message is embedded into a carrier or host file through means such as least-significant bit encoding, appending, or watermarking. Many file types, including audio, video, image, and text, can be embedded into carrier files of equally diverse formats. Today, steganography grows more complex with an increase in open-source applications, which hide data. As applications become more sophisticated, the need to detect, analyze, and stop the flow of dangerous information becomes more crucial.

Due to the increasing need for steganalysis software, companies like Backbone Security have developed programs that detect and decode steganography. StegAlyzer™ is a software program that detects and analyzes suspect files in order to aid law enforcement in the discovery of evidence that may condemn criminals. While there are four programs within the StegAlyzer™ suite, this investigation dealt with its Signature Search (StegAlyzerSS™) and Artifact Scanner (StegAlyzerAS™) due to their abilities to detect steganography applications and the steganography created from these applications.

Several questions were asked in this study: (1) does analysis time change with different carrier and message sizes and formats; (2) how well does StegAlyzerAS™ detect multiple steganography applications; and, (3) can StegAlyzerSS™ detect steganography from these applications? For the first question, a free application named GhostHost was selected to create steganography of differing sizes and formats. The open-source steganography applications chosen for the latter two questions were GhostHost, ImageSpyer G2, OpenStego, Steg, Steganography Studio, Open Puff, Silent Eye, Steghide, and Secret Layer.

StegAlyzerAS was able to identify signatures from five out of nine applications investigated in this study and StegAlyzerSS had a success rate of 33% in identifying steganography created by the applications. StegAlyzerSS was also used to analyze the duration of detection for image steganography created by GhostHost, a steganography appending, open-source application. Analysis time fell within the range of 0.15 and 0.25 seconds regardless of carrier or message file size. A one-way analysis of variance showed that different carrier and message sizes and formats had no statistical effect on analysis time.

Further studies should investigate StegAlyzer’s™ abilities compared to other steganalysis software, such as WetStone’s StegoHunt™ or open-source steganalysis software such as Steganography Studio. StegAlyzer™ is an invaluable tool for investigations of digital crimes, and requires competent analysts to be effective.

Steganography, Steganalysis, Investigation

Digital & Multimedia Sciences Section - 2015

C21 Generating a Corpus of Mobile Forensic Images for Masquerading User Experimentation

Marc Brooks, MS, The MITRE Corporation, 7515 Colshire Drive, Mclean, VA 22102; Justin Grover, MS, The MITRE Corporation, 7515 Colshire Drive, Mclean, VA 22102; Mark D. Guido, MS, The MITRE Corporation, 7515 Colshire Drive, Mclean, VA 22102; Eric Katz, 2099 Malibu Drive, West Lafayette, IN 47906; Jared Ondricek, MS, The MITRE Corporation, 7515 Colshire Drive, Mclean, VA 22102; Marcus Rogers, PhD, Purdue University, 401 N Grant Street, West Lafayette, IN 47907; and Lauren Sharpe, MS, The MITRE Corporation, 7515 Colshire Drive, Mclean, VA 22102*

After attending this presentation, attendees will understand the research outcomes and results of a recently conducted experiment identifying masquerading users on mobile devices using traditional and mobile forensic techniques.

This presentation will impact the forensic science community by providing forensic investigators/researchers with an example of successful human subject experimentation used in support of forensic analysis.

Periodic Mobile Forensics is a research project investigating user behavioral measurement on mobile devices by applying both traditional and mobile forensics processes. Forensic techniques have been applied to an enterprise mobile infrastructure where a mobile on-device agent named TractorBeam was utilized. This agent periodically collects changed storage locations from each device to allow for later image reconstruction and analysis. TractorBeam operates silently in the background during the normal use of the device. TractorBeam provides its collected data periodically to an enterprise infrastructure, which consists of a cloud- or server-based queuing service, a relational database, an analytical framework for running forensic processes, and a Mongo database for storing the analytic output.

Collaborating with Purdue University, a three-month experiment was performed where TractorBeam's operation in a simulated operational setting to identify masquerading users (i.e., users operating the devices other than the enterprise designated mobile device user) was evaluated. It was surmised that even if a masquerading user on an enterprise mobile device lacked malicious intent; this masquerader would still be undesirable to the enterprise. A set of human-subject volunteers were provided with the following: preconfigured mobile devices with cellular voice and data plans, with the TractorBeam agent pre-installed; a simple acceptable-use policy; and deceptive project background information to stimulate normal behavior. TractorBeam transmitted encrypted incremental backups to an Amazon® Web Services cloud instance. In the relational database, redundant information within the collected data was deduplicated, resulting in a 50-times reduction in storage size of the images. Most of those images were rebuilt and a series of developed forensic processes were executed on them, resulting in a Mongo collection of extracted audit data. As a result of the experiment, enough data was collected to successfully reconstruct 821 forensic images, extract over one million audit events, and perform masquerading user analysis. This study characterizes the collected corpus, the extracted audit events, and the performance of TractorBeam throughout the protocol. For masquerading detection, a set of features from the collected audit data was produced and associated those features to user sessions, or periods of device usage. Those sessions and their associated features are being used to train and evaluate a set of classifiers. This analysis is in progress and will be documented in a future paper.

Mobile, Masquerading, Experiment

Digital & Multimedia Sciences Section - 2015

C22 The Intersection of Physical and Digital Security and Investigations

Walter T. Hart, MBA, 149 Hamerton Avenue, San Francisco, CA 94131*

After attending this presentation, attendees will understand some basic principles and behaviors related to physical security and cyber security and how they interact.

This presentation will impact the forensic science community by providing a basic understanding of the common ground and responsibilities in physical and cyber security.

Many organizations treat physical security and cyber security as separate and distinct responsibilities. In fact, the intersection of these security responsibilities is critical to understand. Cyber security practitioners must interact, train, develop policies, and learn with physical security practitioners in order to adequately secure the environment in which they work.

Issues such as entry and search policies and how they relate to cyber security policies regarding external media can and do create conflict between these two groups of practitioners. Indeed, many recent cases have allowed exfiltration of sensitive data aided by the ability of the perpetrator to enter the facility with writable external media.

Additionally, physical security relies heavily on technology, the security of which these practitioners may not fully understand, allowing for physical breaches caused by weak cyber security policies in their security networks. They also require interaction with cyber security, digital forensic, and multimedia practitioners to assist in investigations into physical security incidents.

How this interaction must develop will be addressed as well as suggestions for policy improvement related to these two groups working together.

Physical Security, Digital Security, Cyber Security

Digital & Multimedia Sciences Section - 2015

C23 Memory Forensics: Reliable In-Memory Code Identification Using Relocatable Pointers

*Irfan Ahmed, PhD**, University of New Orleans, 2000 Lakeshore Drive, New Orleans, LA 70148; *Vassil Roussev, PhD*, Computer Science, 2000 Lakeshore Drive, 308 Mathematics Bldg, New Orleans, LA 70148; and *Aisha Ali-Gombe, MS*, University of New Orleans, Computer Science, 308 Mathematics Bldg, 2000 Lakeshore Drive, New Orleans, LA 70148

After attending this presentation, attendees will understand that memory forensics requires the exact knowledge of code that is present in a physical memory in order to apply code-specific data-structure knowledge for extraction of forensic-relevant artifacts. Attendees will learn about the concept of the relocation table and its ubiquitous use in Microsoft® (MS®) Windows® executable files and how relocations can be used to create distinct fingerprints of executable code for extracting their in-memory pages from a memory dump. Using a comprehensive test of more than 50,000 executables, a large-scale experimental validation and statistical analysis of the methodology is presented. It shows that relocation tables are closely tied to the specific version of a code executed in memory and can be used to strongly identify (a piece of) code found during the analysis.

This presentation will impact the forensic science community by discussing a code fingerprinting technique that is able to identify a specific version of code in a memory. Unlike previous techniques, which require parsing of memory contents, disassembly of code, and identification of the address space of kernel and processes, this presentation will show that the derived fingerprints from relocations works reliably on a memory capture without any prior knowledge about the content of the memory. Prior techniques also have a limited focus on identifying operating system code and its specific version. The presented technique works on any relocatable code and is effective in identifying any MS® Windows® executable code.

The relocations are pointers in the code that need to be adjusted depending on where the executable is loaded into the memory. A relocation table in an executable file contains the locations of the pointers in the code, which are the offsets to the pointers from the beginning of the file. The table is only required during the file's load time and is then discarded from the memory. The presented technique extracts the relocation table from the file. It then divides an executable file into memory-size pages and uses relocations to create separate signatures (or fingerprints) for the pages of the executable file. A signature consists of offsets to pointers from the beginning of a page and the pointer values. The signatures are then used to search physical memory page-by-page to find the executable file pages with no intrinsic knowledge about memory content.

The presentation will address a number of additional challenges including paging and Address Space Layout Randomization (ASLR). Most code is, by default, pageable which implies that parts of the executable may not be physically present in volatile memory. This study shows that a *majority-wins* approach is sufficient to overcome this obstacle. ASLR presents a different challenge in that, on every execution, it loads the code starting from a randomly chosen base address and adjusts the necessary pointers in the loaded code. As a result, the representation of the code on-disk and in-memory diverge; however, this study identifies reliable invariants in this process, which enable the correct one-to-one mapping as well as the computation the actual run-time base address.

Code Fingerprinting, Memory Forensics, Relocation Tables

C24 Graphic File Carving Tool Testing

Richard Ayers, MS, 100 Bureau Drive, Mail Stop 8970, Gaithersburg, MD 20899-8970; James R. Lyle, PhD, NIST, 100 Bureau Drive, Mail Stop 8970, Gaithersburg, MD 20899; and Jenise Reyes-Rodriguez, BS, NIST, 100 Bureau Drive, Gaithersburg, MD 20899*

After attending this presentation, attendees will be aware of the importance of tool testing and will have gained an understanding of the file-carving tool-testing process conducted within the Computer Forensics Tool Testing (CFTT) project.

This presentation will impact the forensic science community by increasing awareness of the impact tool testing has on informing the forensic community of tool capabilities and limitations. Test reports provide a foundation for toolmakers to improve tools, help users make informed choices, and provide interested parties with an overview of any anomalies found. This presentation will provide an overview of tools capabilities for carving graphics files and the CFTT test results produced for various tools.

The CFTT project has been researching and testing forensic tools capable of reassembling files from fragments in the absence of file system metadata, typically accomplished by searching an input for files based on content or header/footer file signatures. This presentation discusses all aspects of the testing process that are critical for producing a test report.

A summary for the test results of the graphic file carving tools examined will be discussed for each dd image created for performing the following test cases:

Nofill: Contiguous files with no other content between files.

Simple: Contiguous and sequential fragmented files with content separating the files.

Partial: Contiguous and partial (i.e., only a portion of the file is present) files.

Disordered: contiguous and disordered fragmented files separated by other content.

Braided: Contiguous and intertwined fragmented files.

Not-Shifted: Contiguous files that are aligned on sector boundaries.

Shifted: Contiguous files that are aligned on non-sector boundaries.

Each test report contains an associated table that identifies the test, the total number of files carved, and a classification based upon the data recovered. The categories classifying the recovered data for each test follow:

Viewable — Complete/Minor Alteration: Carved data appears to be unchanged from the original or the changes are so minor that the full content and most attributes of the video are maintained.

Viewable — Incomplete/Major Alteration: Include partial recoveries (i.e., only parts of the file are viewable), scrambled files in which the fragments are assembled incorrectly (making the content of the file unrecognizable), color shifts, and similar changes.

Not Viewable: Describes carved files that are not viewable, could not be opened, or had no content when opened.

False Positive: Reports a count of files that were incorrectly identified.

The presentation gives an overview of the CFTT process as applied to graphic file carving tools while providing information on file carving and scanning unallocated space enabling the recovery of specific file types with based-upon file signatures and various carving schemes.

The test reports are available from the Department of Homeland Security Cyber FETCH web site: <https://www.cyberfetch.org/>.

D1 Vehicle Seat-Adjuster Failure in Collisions: Unreliable Safety Devices

*Mark C. Pozzi, MS**, Sandia Safety Sciences, 2 Marietta Court, Ste A, Edgewood, NM 87015; and *Kenneth J. Saczalski, PhD**, 1440 W Bay Avenue, Newport Beach, CA 92661

The goals of this presentation are to: (1) inform forensic and field investigators for police, medical, and traffic safety organizations how and why various seat adjusters fail in various collisions; (2) teach methods of recognizing, analyzing, and documenting such failures; (3) explain how such seat failures affect vehicle occupant safety; and, (4) demonstrate via static and crash testing how alternative designs prevent such predictable failures.

This presentation will affect the forensic science community by providing information on largely hidden vehicle safety defects that affect the motoring public. Many severe injuries and deaths have occurred due to such failures, which are not adequately addressed by many government or auto-industry safety standards.

Seat adjusters are not merely devices to assist motorist comfort and fit within a vehicle. Vehicle manufacturers warn motorists to never adjust seat tracks, recliners, or other adjusters while vehicles are in motion and that seatbacks must be upright. They warn that any seat movement due to release of a seat adjuster can reduce the effectiveness of seat belts and increase the likelihood of injury; however, the vast majority of seats in vehicles are subject to exactly that kind of predictable unsafe seat movement due to inadequate crashworthiness of seat structures and seat adjusters. Most seats are too weak to be capable of meeting the requirements for occupant protection set forth in the vehicle owner's manual. There are no sensors or warnings provided in vehicles to indicate that seats adjusters are not fully engaged or that seatbacks are not adequately upright while the vehicle is in motion. These seats are legal to sell due to inadequate or non-existent seat safety and occupant protection regulations and resultant lack of meaningful testing. The enhanced potential for serious and fatal injury to front and rear seat occupants, including children, is clearly demonstrated.

Decades of research into vehicle crashworthiness and occupant protection effectiveness of various seat and belt combinations have demonstrated numerous random modes of seat adjuster failure in foreseeable collisions. Over time, seats have grown more complex, often adding vertical and tilt adjusters as well as recliners and latches that allow fold-flat capability of not only rear seats in utility vehicles but also some front seats. This study involves analysis of various seat adjuster failures during static, sled, and crash tests, as well as related forensic evidence found on front and rear seats and vehicle structures during field investigations. This includes: seat track-to-floor anchors; seat track adjusters; seat cushion-to-seat track separation; seat cushion vertical and tilt adjusters; recliner gear, bolt, and frame fracture; and, adjuster friction mechanism slippage. Seat adjusters also fail due to occupant and/or seat belt contact to unshielded controls. Inertial release of seat controls which are engaged merely by spring tension is also a risk. Bending and fracture of inadequate seat frames can contribute to catastrophic failure of one or more seat adjusters, especially in offset and angular impact loading. Angular loading of seats can often reduce static strength capacity by 30%-40% compared to straight rearward loading. One type of seat has demonstrated at least seven random failure modes, often with multiple adjuster failures in one collision. Seats with multiple adjusters or multi-function recliners often show greater potential for failure at lower occupant load levels than those achieved by more basic seats. Seat adjusters have also shown significantly reduced strength, crashworthiness, and reliability if they are placed in less than optimal mechanical engagement, within their normal operating range. All of these factors contribute to the unreliability of seat adjusters as an occupant safety device.

This study shows direct comparisons between evidence found in field investigations of front and rear seat failure and laboratory studies performed to demonstrate the circumstances of the collision. This includes sled testing with adult and child dummies, vehicle-to-vehicle crash testing, and vehicle-to-fixed object crash testing. These seat adjuster failures usually involve rear impacts but have also occurred in front, side, and rollover collisions. Seat adjuster failure modes, seat belt slackening effects, resultant occupant kinematics, ejection, and injury are analyzed in detail. This includes static testing as well as side-by-side dynamic testing of various seat, seat adjuster, and seat belt designs under identical collision circumstances.

Seat-Adjuster Failure, Rear Impact, Vehicle Occupant Injury

Engineering Sciences Section - 2015

D2 Enhanced Injury From Failure of Seats, Seat Belts, and Unsafe Vehicle Interiors

*Mark C. Pozzi, MS**, Sandia Safety Sciences, 2 Marietta Court, Ste A, Edgewood, NM 87015; *Kenneth J. Saczalski, PhD**, 1440 W Bay Avenue, Newport Beach, CA 92661; *Paul Renfro Lewis, Jr., MS**, Bioforensic Consulting, 55 Park Square Court, Ste 207, Roswell, GA 30075; *Todd Saczalski, BSMET*, 140 Calle Irena, Sedona, AZ 863336; and *Charles Dickerson, BS*, 4315 N 36 Street, Phoenix, Arizona 85018

The goal of this presentation is to inform investigators for police, medical, and transportation safety organizations of the hazards presented to vehicle occupants in collisions when seats and seat belts fail. Injuries can be enhanced when such failures allow occupant contact with hazardous structures within vehicle-occupant compartments. The combination of weak seats, slackened seat belts, and unpadding, force-concentrating structures presents extreme hazards to front and rear seat vehicle occupants.

This presentation will impact the forensic science community by educating field investigators, medical personnel, and safety researchers on how to better understand the hazards created when there is a combination of weak seats, slackened seat belts, and unpadding structures within vehicles. These hazards are not permitted in the front of vehicle-occupant compartments, and vehicle seat belts, airbags, and structural padding all combine to prevent such injuries in frontal impacts. No such protection is provided for rear impacts.

Front seat and belt failure in rear impact has been known to cause severe injury and death to both front and rear seat occupants. Several cases of predictable enhanced head and spinal injury have been discovered in vehicles where front seat and seat belt failure was combined with inadequately padded force-concentrating structures in the rear of vehicle occupant compartments. Causation of these enhanced injuries was proven by a combination of accident reconstruction, static testing, and dynamic testing. Prevention of injury by lightweight, technologically and economically feasible means was also demonstrated.

It has been known for decades that head impact into narrow, force-concentrating structures can result in skull fracture, brain injury, spinal injury, and death at much lower load levels than if those same structures were adequately padded or contoured to reduce their lethality. To reduce or eliminate such injuries, FMVSS 201, Occupant Protection from Interior Impact, has been part of the Code of Federal Regulations related to vehicle crashworthiness since 1967. It has required certain interior structures to be effectively padded, flattened, rounded, and otherwise made less lethal when contacted by vehicle occupants whether belted or unbelted. This is why dash panels and other vehicle interior trim is padded and why narrow, projecting controls and other structures have been eliminated in the forward areas of passenger vehicles.

Several contradictions to the well-known foregoing occupant protection principles have been discovered in late model vehicles, in which unpadding, force-concentrating structures have been placed into the path of vehicle occupant heads that are allowed to catapult rearward as a result of predictable front seat and belt failure. These dangerous conditions have occurred in vehicles produced by multiple manufacturers. There have been enhanced brain and spinal injuries and death caused to vehicle occupants that would otherwise not have occurred if the front seat had remained reasonably upright and, therefore, the belts and head restraints would have been effective at protecting the occupant; and if there had been energy-absorbing padding or elimination of the rigid, force-concentrating structures in the rear of the vehicle interior. Some of these force-concentrating rear interior structures are hazardous to all vehicle occupants, including those in the rear seats.

The reason these dangerous conditions are occurring in late model vehicles is that there are not occupant protection standards for rear impact, no dynamic seat or belt performance standards for rear impact, and there are no requirements for equivalent padded structures in the rear of vehicle interiors as those found in the front seating areas.

This study presents the forensic field investigations that have been conducted to identify these dangerous designs, as well as static and dynamic testing that discovered both the failure mode of the seats, head restraints and belts, as well as how to prevent such injuries. Improved seat and head restraint designs were incorporated in the static and dynamic testing to prevent any occupant contact with the force-concentrating structures. Alternative designs that would eliminate the force-concentrating structures in the rear of vehicles were also determined.

Engineering Sciences Section - 2015

This presentation will benefit the forensic science community by showing that these severe hazards exist, why they exist, how they create enhanced injury, and how those injuries can be prevented using lightweight, economically and technologically feasible means. Vehicle crash investigators will learn how to identify vehicle seat and belt failure, vehicle interior occupant contact witness marks, and associated forensic evidence that will allow more accurate assessment of occupant injuries in such circumstances.

Enhanced Injury, Seat and Belt Failure, Unpadded Vehicle Structure

D3 Motorcycle Helmet Translational and Rotational Head Injury Risk Measures Using H-III Head Impact Tests

*Kenneth J. Saczalski, PhD**, 1440 W Bay Avenue, Newport Beach, CA 92661; *Todd Saczalski, BSMET*, 140 Calle Irena, Sedona, AZ 863336; and *Joseph L. Burton, MD*, 13784 Highway 9, Alpharetta, GA 30004

After attending this presentation, attendees will understand an experimental pendulum impact test method, using H-III biofidelic surrogate head and neck components, for measuring impact and rotational head injury risks of motorcycle helmet safety performance.

This presentation will impact the forensic science community by illustrating how this test method provides a means for efficiently evaluating helmet safety and injury risks related to both translational and rotational head/brain injury mechanisms by utilizing a human-responding H-III head and neck with a multidimensional pendulum impact device that also allows for full-face helmet safety evaluation not tested in current European and United States helmet certification standards.

Concussion and severe head injuries sustained by helmeted motorcycle riders are often related to both direct translational contact impact and brain rotational shearing mechanisms. Research by Hodgson (1975), Gennarelli, (1982), and Ryan (1994), among others, have addressed biomechanical injury risk levels of direct impact and rotational effects on humans.¹⁻³ More recent studies by O’Riordain (2003) and Antona-Makoshi et al. (2013) have also studied brain injury risk as functions of both direct impact and rotational effects.⁴⁻⁵ Unfortunately, current helmet certification standards do not test with Human Responding (HR) head forms nor do these criteria measure multi-directional impact conditions necessary to evaluate both direct contact impact and rotational effects. Also, the current helmet certification impact test devices do not enable measures of “full-face” head impact modes.

In this study, a 3D pendulum impact device, with an HR Hybrid-III head form and neck, is used to study multi-axial direct contact impact and head rotational effects on helmet safety. The H-III head is instrumented with a tri-axial accelerometer and multi-axial angular motion recording devices that allow measures of the Head Injury Criteria (HIC) and angular velocity versus angular acceleration levels for the helmeted head form when subjected to various impact conditions including full-face frontal loads. The test impact speeds and energy levels are comparable to current helmet certification test criteria. The figure below shows a sequence of photo clips taken from one of the pendulum impact tests of this study that involved a “full-face” 110 Joule (J) impact to a helmet when impacted at 25kph. The photos show, from left to right, film clips at: 50ms before impact; 12ms into the impact; and, 100ms after impact. The peak acceleration was 145 G’s at 11.4ms, and the 15ms calculated HIC was 758. The head pitch-rotation rate was 19.8r/s at 10ms and the angular acceleration was 11,210r/s/s at 11.5ms.

In addition to the above 25kph test, another full-frontal impact test was conducted on the same model helmet but at an impact speed of 28.4kph to examine helmet safety performance at a higher 150J impact energy level. In this test, the peak resultant acceleration was 266 G’s at 4.6ms, and the 15ms calculated HIC was 2009. The test HIC levels of 758 and 2009 both violate the NHTSA recommended head injury limit of 700 and indicate danger of a severe head injury. The head pitch-rotation rate in this second impact test was 28.9r/s at 4.9ms and the angular acceleration reached 13,776r/s/s at 4.1ms. The measured acceleration-time data from the above two tests were at the upper tolerance level for Acute Sub-Dural Hematoma (ASDH) and Sub-Arachnoid Hematoma (SAH) as predicted by Auer et al. (2001) based on head injury reconstructions from 25 fatal pedestrian accidents.⁶ With regard to Diffuse Axonal Injury (DAI) effects, the rotational acceleration measures for the first test were indicative of a classical concussion level as defined by Gennarelli. The much higher rotational acceleration measures for the second test were indicative of a “mild” DAI level as defined by the Gennarelli reference.

Engineering Sciences Section - 2015

Finally, the above ASDH, SAH, and DAI injury risk findings derived from the direct contact impact and rotational measures obtained from the two full-frontal impact tests on the helmet model shown in the figure above were consistent with the medical record descriptions related to severe brain injuries sustained by a motorcycle rider wearing the same model helmet in an actual accident. Damage to the accident helmet indicated primary impact to the chin bar and forehead full-frontal region of the helmet, like the region tested on the exemplar helmets. The correlation of the tests with the actual accident injuries suggests that the pendulum impact apparatus, with the human responding H-III head form and H-III neck, provide a reasonable method for assessment of overall helmet safety performance as related to both direct contact impact and rotational acceleration forces in all modes of impact, including full-frontal, and improves on current helmet certification test limitations.

Head Injury, Helmet Testing, Impact Analysis

Engineering Sciences Section - 2015

D4 Ejection of Belted Vehicle Occupants Due to Seat and Belt Failure in Rear Impacts

Mark C. Pozzi, MS, Sandia Safety Sciences, 2 Marietta Court, Ste A, Edgewood, NM 87015; Paul Renfro Lewis, Jr., MS*, Bioforensic Consulting, 55 Park Square Court, Ste 207, Roswell, GA 30075; and Kenneth J. Saczalski, PhD, 1440 W Bay Avenue, Newport Beach, CA 92661*

The goal of this presentation is to inform attendees how and why restrained vehicle occupants can be partially or completely ejected from vehicles as a direct result of seat failure which can also cause failure of vehicle-anchored seat belts by causing excessive belt slack.

This presentation will impact the forensic science community by illustrating how seat belts can be defeated by weak seats in vehicles. Defeat of the seat belts can lead to the partial or complete ejection of initially restrained occupants.

Seat belts, seats, and head restraints are equally critical components of vehicle occupant protection systems. Based on human tolerance testing, Federal Motor Vehicle Safety Standard (FMVSS) 210 requires lap/torso belts to withstand 6,000 pounds of forward static load. Belt webbing and anchorages therefore are rarely overloaded in survivable front and side collisions. At 30mph ΔV , only 1" of belt slack increases vehicle occupant injury by 50%, and 4" of belt slack is equivalent to being unbelted. Pretensioners may minimize belt slack in frontal impacts where airbag deployments occur. Pretensioners rarely activate in rear impacts and have proven to be inadequate to provide belt effectiveness if significant seat deformation occurs.

Vehicle manufacturers warn against adjusting seats when vehicles are in motion because of increased injury risk and decreased effectiveness of seat belts. FMVSS 207 requires less than 300 pounds static load capacity for seats and does not consider human tolerance to impact or presence of an occupant in the seat. No occupant protection requirements exist for rear impact or rollover. Therefore, seats, head restraints, and seat belts predictably fail in moderate rear impacts and rollovers. When a seat fails rearward, head restraints cannot function and dangerous amounts of slack are created in any vehicle-anchored seat belt system, rendering the belt ineffective in exactly the manner warned about by manufacturers. Seven to 14 inches of static belt slack is created solely by recline of the front seat. Many vehicles allow ten or more inches of additional rearward belt buckle displacement. Any of these belt-slackening mechanisms created by seat failure will allow the lap belt to easily slip off the pelvis, negating any effective restraint. Mis-positioned lap belts cause serious or fatal injury from submarining as well as partial or complete ejection in subsequent collision or rollover. In 1967 FMVSS 209.4.1, it is required that lap belts remain on the pelvis at all times during collision or rollover. Despite objection from the National Transportation Safety Board (NTSB) and others, and decades of consistently poor crash test results proving this danger, in 1998 vehicle manufacturers successfully petitioned the United States Department of Transportation to rescind this critical dynamic seat belt performance requirement. No conceivable benefit to motorist safety occurred.

This study shows how and why predictable seat/head restraint failure and resultant dangerous seat belt slackening have allowed partial and complete ejection of belted occupants in crash testing and real-world collisions and rollovers. There have been numerous crashes and rollovers investigated for this study where belts were properly worn and seats were upright prior to the crash. The belts remain buckled but due to seat failure and belt slack the occupant was ejected either into the rear interior, other occupants, and/or completely out of the vehicle. In several instances, lighter-weight occupants, or similar-size occupants who loaded into stronger seat structures, were effectively restrained and protected by seats and head restraints that remained upright and belts that therefore remained effective. Published crash and sled test research since the 1960s has consistently demonstrated that when seats fail, no effective lap belt loads are generated prior to occupant contact with either the rear seat, other occupants, and/or ejection from the vehicle.

Effective countermeasures which prevent seat and belt failure are presented in this current study, utilizing recent dynamic side-by-side testing of crashworthy seats and head restraints, resulting in belts that function as intended. This is compared with **Original Equipment Manufacturer (OEM)** collapsing seats, head restraints, and resultant slackened seat belts that allow ejection. There is also comparison of biofidelic dummies having articulating pelvic and leg structures with non-biofidelic dummies that artificially snag lap belts.

The forensic community will benefit from this presentation by learning how to recognize forensic evidence associated with seat and belt failure, including deformation and witness marks on vehicle interiors, seats, and belts. Investigators will learn how and why ejection of belted occupants readily occurs in passenger cars, vans, and light trucks. Fatal injuries have occurred to such occupants while those in upright seats beside them were unhurt.

D5 Vehicular Rear-Impact Accident Reconstruction: Validation by Crash, Sled, and Static Testing

Todd Saczalski, BSMET, 140 Calle Irena, Sedona, AZ 863336; Mark C. Pozzi, MS*, Sandia Safety Sciences, 2 Marietta Court, Ste A, Edgewood, NM 87015; Charles Dickerson, BS, 4315 N 36 Street, Phoenix, Arizona 85018; and Kenneth J. Saczalski, PhD, 1440 W Bay Avenue, Newport Beach, CA 92661*

The goal of this presentation is to inform attendees of details concerning how accurate reconstruction of vehicular rear impacts is performed and how validation of calculated results has been determined via repeatable scientific testing.

This presentation will impact the forensic science community by providing knowledge about the proper manner in which to investigate, analyze, and reconstruct rear-impact collisions. These are common collisions that are inadequately represented in research efforts and safety emphasis on both governmental and automobile manufacturing levels.

Rear impacts are among the most common crash modes, yet they receive relatively little attention from government safety regulators and auto manufacturers. With relatively rare exceptions, the only common rear crash testing done is per Federal Motor Vehicle Safety Standard (FMVSS) 301-75 to evaluate fuel system integrity. Such tests typically utilize rear moving barriers with little to no instrumentation and net impact severity tends to be only about 60% or less of typical frontal impacts at the same contact velocity. Such impacts rarely are conducted at angular principle direction of force. There are no occupant protection or dynamic head restraint requirements for rear impact and static strength requirements for seats are less than 10% of those for torso belts. Rear bumpers often are made of very weak composite materials and plastics which contribute to override and intrusion of rear cargo compartments and occupant survival space. As a result, rear impacts of otherwise readily survivable severity commonly result in serious or fatal injury to front and rear occupants, including children, due to failures of front and rear seats, slackened seat belts, and occupant compartment intrusion.

Compounding the foregoing relative lack of information concerning vehicle rear crush characteristics is the fact that almost all vehicles utilize front engines with firewalls and structural bulkheads between the engine and passenger compartments, while the equivalent rear cargo areas are full of air. Utility and van-type vehicles typically have nothing between the seats and the cargo area and most passenger cars tend to have open bulkheads between the rear seat and the trunk. Therefore, the risk of rear intrusion tends to be greater than frontal intrusion in a given impact severity, particularly if there is override of the rear bumper. Approximately two-thirds or more of rear structural integrity is carried in the frame and bumper areas.

This study involves various types of vehicles and impact severities in which a combination of crash, sled, and static testing was conducted on a given vehicle design. The various tests served to validate the accident reconstruction analysis. This research showed that in many instances, "default" stiffness coefficients utilized by common accident reconstruction computer programs tend to overestimate actual rear impact severity. The similarity between predicted crash pulse amplitude and duration is also demonstrated via direct comparison between calculated values and test data. Static testing of seats can also serve to validate calculated crash severity values by determining the seat deformation caused by occupant loading under known conditions with the evidence found in crashed vehicles.

This study demonstrates the forensic science involved in determining the accurate severity of foreseeable rear collisions involving several common types of vehicles. Current methods used to determine rear crash severity may overestimate collision velocities, thus giving the incorrect impression that severe injuries or death were caused in much higher-speed crashes than actually occurred. The incorrect conclusion is that vehicle structures and seats are actually performing far better than they actually do in the real world. The safety implications for motorists in millions of reasonably similar vehicles under similar impact conditions is clear. The design and testing process (and lack thereof) used to develop these vehicles allow common failures of seats, seat belts, and rear structures. The testing shown in this study clearly demonstrates that what should be among the most readily survivable crash modes commonly results in severe or fatal injuries to vehicle occupants. These failures could be prevented if properly tested prior to initial vehicle production.

Accident Reconstruction, Rear Impact, Crash and Sled Testing

D6 Crash Test Verification of Offset Rear-Impact Accident Reconstruction and Crashworthiness-Design Concepts

Robert L. Anderson, MS*, PO Box 1208, Scottsdale, AZ 85252; Kenneth J. Saczalski, PhD*, 1440 W Bay Avenue, Newport Beach, CA 92661; Todd Saczalski, BSMET, 140 Calle Irena, Sedona, AZ 863336; Russell L. Anderson, MS, PO Box 7185, Tempe, AZ 85281; Mark C. Pozzi, MS, Sandia Safety Sciences, 2 Marietta Court, Ste A, Edgewood, NM 87015; and Peter E. Baray, 8018 E Cyprus, Scottsdale, AZ 85257

After attending this presentation, attendees will be presented with a vehicle-to-vehicle crash test methodology for validating physics-based reconstruction of offset rear-impact override crush accidents, with verifications of occupant injury analysis, a demonstration of safer available alternative vehicle designs, and the benefits of using basic, accepted crashworthiness-design concepts.

This presentation will impact the forensic science community by explaining how the crash test method provides a means for scientifically verifying accident reconstructions with correlation of injury measures, as well as demonstrating safety improvements and reduced injury risks related to following well-established, good crashworthiness-design concepts.

In this study, a physics-based accident reconstruction was performed on a rear-impacted, four-door sedan vehicle that was struck off-set to the right rear half by a Sports Utility Vehicle (SUV) that over-rode the rear bumper and trunk floor structure. This allowed the sedan's weaker sheet-metal fender material to easily crush and allow displacement of the rear shock tower structure into the right-rear occupant space. The sedan had two average-size males in the front and three smaller rear seat occupants. During the crash, the occupied front seats yielded rearward into rear occupant space. Simultaneously, intrusion of the right-rear occupant space by the shock-tower structure shoved the right rear 13-year-old forward toward the rearward collapsing front seat and occupant. As a result of the above occupant space violations, the right-rear occupant received a severe disabling head injury. In contrast, the front occupants and other two rear occupants, who were located farther from the right-rear penetration, did not receive any permanent injuries. In order to understand the engineering parameters that led to the injury of only the right-rear occupant, a reconstruction of the accident was performed by using energy and momentum balance principles. The reconstruction analysis (see Figure 1 diagram) indicated that the SUV impacted into the stationary sedan right-rear at 54kph.

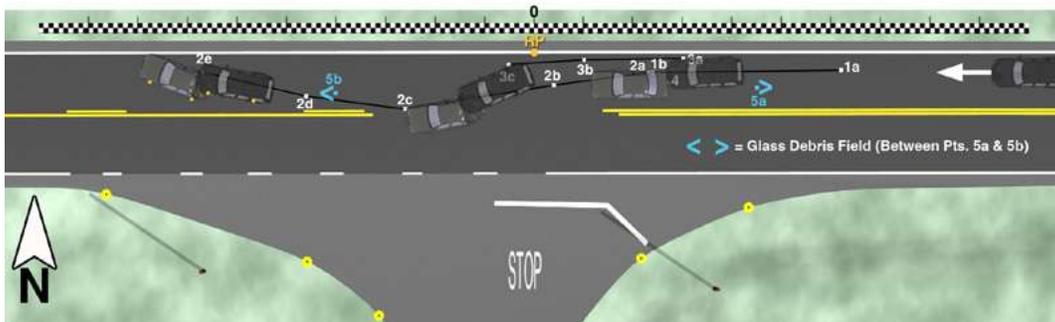

Figure 1: Reconstruction Diagram of Right Rear 50% Off-Set Overlap Rear Impact of SUV into 4-Door Sedan.

A vehicle-to-vehicle confirmation crash test, with instrumented surrogates, was run to verify the reconstruction impact speed and show consistency of surrogate injury measures with accident occupant-injury levels as further proof of the analysis. Figure 2 shows a comparison of the actual accident vehicle damage with the sedan used in this crash test. Figure 3 shows the pre-test positions of the rear seated surrogates and also a photo clip from the high-speed interior camera recorded at 173 milliseconds after impact. The 173ms clip shows the left side of the right-rear surrogate head (red chalked) turned toward the right and striking the back of the right-front surrogate head (blue chalked), and the front seat headrest, due to the inertial rearward loading of the front occupant while the right-rear surrogate was being shoved forward from the rear intrusion. The Head Injury Criteria (HIC) measures of this test, like the accident, indicated that only the right-rear surrogate received a severe HIC level of 1,217.4 (i.e., in violation of the National Highway Traffic Safety Administration (NHTSA) injury level), with a dangerously high-peak G resultant head load of 281 G's.

In addition to the above reconstruction confirmation test, two other tests were also run with the SUV impacting offset into the right-rear half of a four-door sedan at 54kph. One test was run with a crashworthy modified exemplar of the accident vehicle to demonstrate how good crashworthiness redesign of the **Original Equipment Manufacturer (OEM)** vehicle could have been utilized, with state-of-the-art concepts recommended in the 1960s and 1970s, to eliminate the right-rear occupant head injury caused by the space-intrusion dangers of the accident vehicle design.¹⁻⁴ Another repeat 54kph test was also run, but in this test the struck accident vehicle design was replaced by a different commercially available model year OEM European designed four-door sedan, which demonstrated how a vehicle with well-designed barrier resistance and stronger less-rearward yielding front seats could have also eliminated the injury sustained by the right-rear teenager. In both of these tests, the front and rear intrusion, and violation of the rear-seated occupant safety zone, was reduced such that none of the rear-seated surrogates had injurious head contact with the front seats or front occupants.

Figure 2: Comparison of Accident Vehicle Right Side Damage (Blue Vehicle) with Confirmation Test Vehicle.

Figure 3: Pre-Test Surrogate Positions (Left Side Photo) and Confirmation Test Impact Intrusion Photo at 173ms.

Engineering Sciences Section - 2015

D7 Biomechanical Evaluation of Pediatric-Inflicted Head Trauma

*John D. Lloyd, PhD**, 32824 Michigan Avenue, San Antonio, FL 33576; and *William E. Lee III, PhD*, University of South Florida, College of Engineering, Tampa, FL 33620

After attending this presentation, attendees will have an appreciation for biomechanical evaluations that can be applied in order to objectively determine the mechanical causation of inflicted vs. accidental head trauma in a pediatric population.

This presentation will impact the forensic science community by informing attendees that in cases of head trauma in infants and young children, it is often alleged that the parent or care provider struck the child victim with their hand or with or against a hard surface, causing serious and sometimes fatal bodily injury. By performing a systematic biomechanical evaluation, this presentation will quantify the risk of head and brain injury associated with such mechanisms of injury.

Methods: Two adult male investigators served as participants; neither had any physical disabilities that might affect their performance. An instrumented Child Restraint and Airbag Interaction (CRABI) -12 biofidelic mannequin, of height 0.75m and mass 10.0kg, was utilized as the infant surrogate. A 500G piezo-electric tri-axial accelerometer was installed at the Center of Mass (CoM) of the CRABI headform along with a tri-axial digital gyroscope, in accordance with the **Society of Automotive Engineers** (SAE) J211.

Eight conditions were investigated, including striking the head with both an open hand and baseball bat as well as impacting the mannequin head against interior wall structures, both on and between supporting studs. Such walls were manufactured for the purpose of this study using 2"x4" white wood with both 16" Outside Corner (OC) and 24" OC separation between vertical studs, over which 3/8" and 1/2" gypsum drywall was fastened in accordance with state building codes. Participants were instructed to impart gentle, moderate, and vigorous impacts on the infant surrogate, repeated five times for each of the eight conditions, resulting in a total 240 trials.

Results: Data from both the analog linear accelerometer and digital gyroscope was acquired at 10,000Hz, per channel, using LabVIEW™ and filtered in MATLAB® using a phase-less 4th-order Butterworth filter with a 1650Hz cutoff frequency, per SAE J211. Head linear acceleration and angular velocities were recorded, angular acceleration was derived, peak magnitude values were calculated, and Head Injury Criterion (HIC15) computed. Descriptive statistics are reported across repeated trials and participants.

Conclusions: Forces associated with linear acceleration are typically responsible for focal injuries, including subgaleal hematomas, lacerations, skull fractures, and brain contusions, whereas forces associated with rotational inertia account for diffuse injuries, including concussive brain insult, axonal injury, and bridging vein rupture, leading to space-occupying subdural hematomas. Findings from this biomechanical evaluation can be applied to objectively determine the mechanical causation of inflicted trauma from claimed accidental reasons.

D8 Low-Energy Bone Fractures: Part III

David Pienkowski, PhD, University of Kentucky, AB Chandler Hospital, Rm MN 564, Lexington, KY 40536-0298; and Hartmut Malluche, MD, University of Kentucky, Chandler Medical Center, 800 Rose Street, Lexington, KY 40536*

The goals of this presentation are to raise attendees' awareness of bone microdamage, illustrate how above-normal levels of bone microdamage are linked to altered load-bearing mechanical competence, and thereby help the forensic investigator understand how excess levels of microdamage may partially explain low-energy bone fractures.

This presentation will impact the forensic science community by providing a partial explanation for seeming incongruities among low-energy events, reconstruction-derived traumatic event energy (or force) amplitudes, and bone fractures. Bone fractures accompanying low-energy trauma are perplexing to the forensic investigator. Ostensible disparities between the energy (or force) amplitude of the traumatic event and the level of injury can often lead to uncertainty regarding the facts of the event or the validity of the reconstruction.

Application of service loads to engineering structures creates stresses in the constituent materials. These stresses generate material defects which, if accumulated, result in reduced structural stiffness, diminished load-bearing capacity, and may eventually lead to catastrophic failure.

Bone is unique among engineering structures because of its capacity for self-repair of defects caused by physiologic loading. These defects are known as "microdamage" and consist of observable microcracks and not-so-readily observed diffuse damage. Microcracks are quantified by crack number, crack length, and number/length density distributions. Bone microdamage is self-repaired by bone turnover, a complimentary set of on-going cellular events consisting of bone resorption (targeted local destruction of bone with microdamage) followed by bone matrix formation (production of new organic material for subsequent mineralization and maturation into mechanically competent bone). Normal bone turnover prevents damage accumulation from reaching critical levels and confers bone with the biomechanical properties needed to resist excess deformation and avoid fracture.

Rates of bone formation and resorption must be maintained, from both relative and absolute perspectives, to sustain these biomechanical properties. Relative rates of resorption and formation must be equal to avoid losing or gaining bone mass. Absolute rates of turnover must also be controlled to avoid premature bone resorption or prevent microdamage accumulation. Specifically, if the rate of bone turnover is inadequate, then the rate of microdamage repair is less than the rate of microdamage creation and the net amount of microdamage increases. Unrepaired microcracks will increase in length while bone is physiologically stressed and these cracks will eventually coalesce to form larger cracks that could become macroscopic. Thus, bone with above-normal levels of microdamage will have a reduced load-bearing mechanical competence, a diminished injury threshold, and may catastrophically fail (fracture) when subjected to low-energy trauma.

The forensic investigator should appreciate the variety of bone-quality factors, including microdamage, which collectively govern the mechanical competence of this organ. To reconcile the seeming disparities between fracture and low-energy trauma, the forensic investigator should search for mechanisms linked to abnormal bone turnover. This search should begin with a review of the subject's medical history because low bone turnover is a "silent" phenomenon that accompanies particular diseases or therapies. Excess consumption of certain anti-osteoporosis medications, for example, is known to cause low bone turnover. Advanced age also is associated with low bone turnover. A more thorough investigation requires a surgically procured bone sample upon which histological processing and quantitative microscopic analytical measurement methods are employed to quantify the distributions of mean crack number, length, and density.

The material quality analytical approach described in this and related prior "low-energy bone fracture" presentations offer the forensic investigator a general tool for reconciling low-energy traumatic events with seemingly incongruous injuries in other non-osseous tissues or organs.

D9 Biomechanics of Short Falls in Children

John D. Lloyd, PhD, 32824 Michigan Avenue, San Antonio, FL 33576*

After attending this presentation, attendees will comprehend the risk of traumatic head and brain injuries in a pediatric population associated with short household falls.

This presentation will impact the forensic science community by informing attendees of the mechanisms of head and brain injuries in pediatric populations and the risks associated with short falls.

Introduction: This study involved systematic assessments of falls from heights ranging from two to six feet onto varying flooring surfaces including concrete, linoleum, apartment-grade carpeting with underlay, Berber carpet with underlay, commercial carpeting without pad, and wood laminate.

Methods: A Child Restraint and Airbag Interaction (CRABI) -12 biofidelic mannequin (29.5in/22lb) and a Hybrid III three-year-old (37.2in/35.65lb) biofidelic mannequin were used during this systematic evaluation of short falls. A tri-axial piezo electric accelerometer, calibrated and certified by PCB® Piezotronics, was installed at the center of mass of the CRABI headform, in accordance with convention described in the **Society of Automotive Engineers** (SAE) J211 along with an InvenSense® tri-axial digital gyroscope. Still photography and high-speed video were used to record the fall sequences.

A height-adjustable platform was used to represent the fall surface. The platform has trap doors, which are held in place by electromagnets. Interruption of power to the electromagnets causes the sprung trapdoors to open instantaneously, thereby initiating the fall sequence. To investigate biomechanical mechanisms of injury associated with short falls in children, 175 trials were completed.

Data from the tri-axial piezo-electric accelerometer, mounted in the head of the biofidelic mannequin, were acquired at a rate of 10,000 samples per second using LabVIEW® software. Data from the Microelectromechanical System (MEMS) tri-axial gyroscope were acquired at 3,800Hz per channel. Raw data were displayed on-screen for visual verification. These data were analyzed using MATLAB®, including Fast Fourier Transform analysis to visualize the frequency spectrum of the data, followed by phase-less filtering using a 4th-order low-pass Butterworth filter with a cut-off frequency of 1650Hz. The peak magnitude value of head linear and angular acceleration components were derived and Head Injury Criterion (HIC) computed.

Results: Both the CRABI-12 infant representative and Hybrid III toddler representative exceeded injury threshold values from a fall height of only two feet (61cm), based on peak magnitude linear acceleration and HIC, which indicates that such short falls can cause substantial head/brain injuries in young children.

Conclusions: Results clearly show that household short falls events do exceed established thresholds of injury based on linear and angular accelerations. Furthermore, kinematic measures associated with household short falls are comparable to high-risk adult sporting activities, such as a typical boxing punch or a concussive tackle in college football. Based upon these evaluations and associated results presented herein, it is the expressed conclusion that household short falls present a very real and significant risk of head and brain injury among infants and toddlers.

D10 An Examination of Dynamic Mechanical Properties and the Strain State Evaluation Technique of Soft Tissue

Yasumi Ito, PhD, Furo-cho, Chikusa-ku, Nagoya, Aichi 464-8603, JAPAN; Ryotaro Kishida, University of Yamanashi, 4-3-11, Takeda, Kofu-shi, Yamanashi Prefecture 400-8511, JAPAN; Yoshiyuki Kagiya, PhD, University of Yamanashi, 4-3-11 Takeda, Kofu-shi 400-0001, JAPAN; and Shohei Daimaru, 4-3-11 Takeda, Kofu-shi, Yamanashi-ken 400-0001, JAPAN*

After attending this presentation, attendees will understand the evaluation method of the dynamic mechanical properties of soft tissue.

This presentation will impact the forensic science community by providing the physical model of personal injury evaluation that takes into account the dynamic mechanical properties of soft biological tissue.

To clarify the presence or absence of murderous intent in cases of murder, attempted murder, and injury, the relationship between personal injury and external forces has been extensively studied for a long time in university forensics medicine classrooms and by the police. As a result, it has been revealed that the presence of soft tissue such as skin and muscle has a great effect on the presence or absence of bone fracture resulting from a dynamic load; it is therefore important that the physical model used for personal injury considers soft tissue. Since the technique of measuring dynamic mechanical properties of soft tissue does not yet exist, the effect has not been quantified to date. In addition, data regarding the stress-strain properties and viscoelastic properties of skin are essential to evaluate skin damage caused by external forces, but it is difficult to accurately measure and evaluate the strain in the skin. Because the handling of soft biological tissues is difficult, soft tissue is usually not taken into account in the physical model of personal injury evaluation. For example, there is the Hybrid III 50th dummy that is used to evaluate personal injury in car accidents. This is used not only in automotive frontal collision tests, but also in the evaluation of human body damage caused by impact, drop, fall, vibration, etc.; however, the presence of soft tissue is not considered. The evaluation of safety standards for life-support robots conforming to the International Organization for Standardization 13482 uses a “dummy skin” that utilizes substitute materials to reproduce the mechanical properties of soft tissue. Dummy skin uses human skin gel as artificial subcutaneous tissue and is an alternative material used for considering the influence of a static external force on soft tissue. Currently, the evaluation of human skin gel remains primarily a static evaluation technique and it has been questioned whether the dynamic mechanical properties of soft tissue with respect to dynamic loads such as those that occur during personal injury can be accurately reproduced. It becomes necessary to consider alternative materials to reproduce the stress-strain properties of skin and the dynamic mechanical properties of soft tissues, and the goal is to quantify these properties for the development of alternative substitute materials.

In this study, the dynamic viscoelastic properties of soft tissue was measured using a rheometer and a durometer and the evaluation methods were studied. The rheometer has so far been used to measure the dynamic viscoelastic properties of industrial materials having fluidity, such as grease; however, improvements in recent years have resulted in its use for soft solid materials such as rubber, resulting in this study attempting to measure the viscoelastic properties of skin using a rheometer. In addition, the transformation of artificial skin was measured using a strain gauge and the evaluation technique of the stress-strain state was measured. Generally, the strain gauge, typically used to measure small deformation strain, cannot adapt itself to the large deformation field of soft tissue. In order to correctly evaluate the strain state of the skin surface, measurement was therefore attempted using a bonding agent as a material to promote reduction in the strain between the strain gauge and the artificial skin. It became clear from comparing the dynamic mechanical properties of the human arm hardness-equivalent artificial skin that its dynamic viscoelastic properties were considerably different from those of real skin. When the tension of the skin surface of humans was reproduced in the artificial skin, values equal to the result of a measurement of the human arm were obtained. Based on that result, it was suggested that the tension of the skin surface has a significant impact on the mechanical properties of human skin. It was revealed that when artificial skin is used in personal injury evaluation, not only is the material important but also the skin tension.

D11 Biomechanical, Mechanical, and Epidemiologic Characteristics of Low-Speed Rear-Impact Collisions

Michael Freeman, MD, PhD*, 425 NW 10th Avenue, Ste 306, Portland, OR 97209

The goal of this presentation is to provide a reliable description of the mechanical, biomechanical, and injury-risk characteristics of minimal and no-damage rear-impact collisions based on an analysis of epidemiologic data.

This presentation will impact the forensic science community by demonstrating a validated methodology for investigating and describing the dynamic vehicle and occupant characteristics of minimal and no-damage bumper-to-bumper, rear-impact collisions as well as the injury risk associated with such collisions.

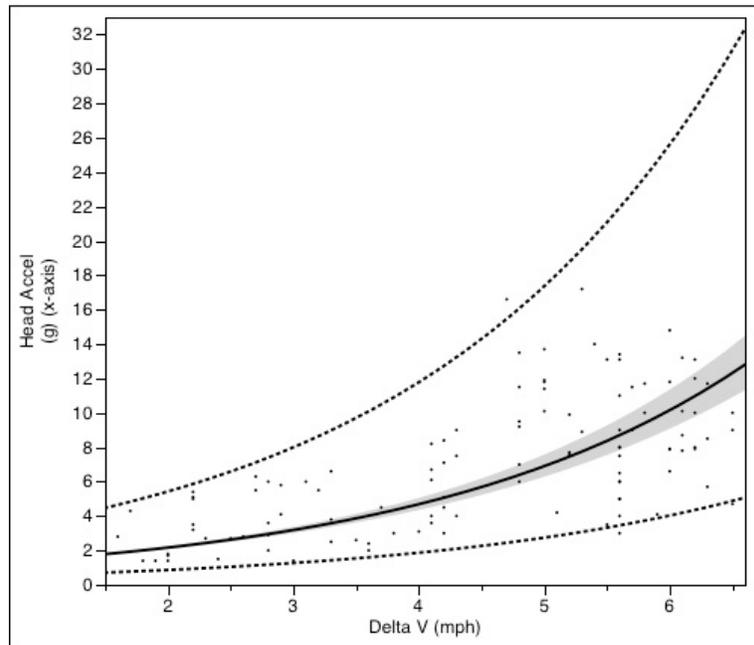

Bumper-to-bumper, rear-impact collisions are unique events that can result in substantial occupant forces while leaving little physical evidence of the collision. Highly elastic bumper components protect the vehicle from visible damage in ≤ 10 mph (16km/h) closing speed and ≤ 8 mph (13km/h) delta V collisions. Precise reconstruction of the delta V of the target vehicle is challenging, as a 3mph delta V crash can leave the same degree and pattern of physical evidence as a 7mph delta V crash (little to none); however, the energy of the latter collision is more than four times greater than the former. Absent multiple full-scale reenactments of the collision, commonly employed reconstruction methods, such as a Mass, Energy, and Restitution (MER) or conservation of momentum calculation, are error-prone because of the speculative basis of some of the critical input variables (closing speed, coefficient of restitution, etc.).

Regardless of the shortcomings, such reconstructions are common in litigation involving minimal damage collisions. This practice is in part due to the fact that it is not uncommon to see claims for injuries in such collisions that are significant, including claims of spinal disk derangement resulting in surgery. The most common purpose of the reconstruction is to estimate vehicle forces, given in terms of acceleration (g). Vehicle acceleration is often used for an inference regarding occupant forces, which are often used to estimate the injury risk of the collision. The relationship between the vehicle delta V and acceleration is based on an assumption regarding the duration of the crash pulse. The method of estimating the occupant acceleration is often unspecified, and typically estimated as equal to two or more times the average vehicle acceleration. The estimate of injury risk from the delta V is most commonly based on the lack of significant injury reported in full-scale human volunteer crash testing and the estimate of injury risk from assumed occupant acceleration is based on comparisons with reported accelerations of daily activities and other non-injurious events.

There are available data sources for estimating all of the above-mentioned parameters of rear-impact collisions, thus eliminating the speculation inherent in the approach described above. Several researchers have examined and described vehicle dynamics associated with low-speed rear-impact collisions via information collected contemporaneously by data event recorders in the vehicles and matched the vehicle information to injury outcome and duration.^{1,2} Other researchers have described the results of volunteer crash testing such that the range of occupant acceleration at a specific delta V can be estimated.³ The purpose of the present investigation is to describe the range of vehicle and occupant dynamic and injury response to a range of rear-impact-related delta Vs associated with minimal and no-damage collisions (3-7mph delta V (5-11km/h)), based on an analysis of previously published observational data. The statistical methods used for the continuous variable outcomes were regression utilizing a general linear model and for dichotomous outcomes binomial logistic regression (JMP®, Version 11).

Delta V (mph, (km/h))	Peak vehicle accel. (g)	Peak occupant head acc. (g)	Crash pulse duration (msec)	Any injury %	Injury >6 months %	Cervical disk injury %
3 (4.8)	6.1 (5.5, 6.7)	4.4 (3.5, 5.9)	55.8 (52.0, 59.6)	24.4 (14.8, 37.4)	1.9 (0.5, 6.8)	1.6 (0.3, 7.3)
4 (6.4)	6.7 (6.2, 7.2)	5.4 (4.5, 7.0)	61.3 (57.9, 64.7)	29.3 (19.6, 41.5)	2.5 (0.7, 8.2)	1.9 (0.5, 7.9)
5 (8.0)	7.2 (6.8, 7.7)	7.2 (6.0, 9.1)	66.7 (63.6, 69.8)	34.9 (25.0, 46.4)	3.5 (1.2, 9.8)	2.5 (0.7, 8.6)
6 (9.6)	7.8 (7.4, 8.2)	10.6 (7.9, 15.9)	79.2 (62.2, 75.2)	40.9 (30.4, 52.3)	4.7 (1.8, 11.8)	3.0 (0.9, 9.3)
7 (11.2)	8.3 (7.9, 8.7)	13 (10, 20)	77.6 (74.6, 80.6)	47.2 (35.5, 59.1)	6.4 (2.7, 14.2)	3.7 (1.3, 10.3)

The above table depicts the results of the analysis of event data recorder-reported findings and the associated medically observed outcomes in 114 occupants exposed to rear-impact collisions. The reported vehicle accelerations were based on a 3g recording threshold, which may have affected the speed change calculation. The risk of cervical disk injury is based on the classification of an injury as a “WAD III,” which includes findings of neurologic involvement. Peak head acceleration is based on the results of 93 volunteer crash tests. The values for occupant acceleration at 7mph delta V are estimated due to excessive variance. The values in brackets are the 95% confidence interval for the point estimate.

The above graph demonstrates the curvilinear relationship between vehicle delta V and peak head acceleration in 93 human volunteer crash tests. The shaded section is the 95% confidence interval, and the dotted line is the predictive interval depicting the likely range of accelerations in the general population.

This presentation will demonstrate the mechanical, biomechanical, and injury risk characteristics of minimal and no-damage rear-impact collisions.

D12 Biomechanics of Spinal Injury

Harold Franck, MSEE, PE, Advanced Engineering Associates, Inc, 4713 MacCorkle Avenue, SE, Charleston, WV 25304; and Darren Franck, MSME, Advanced Engineering Associates, Inc, 4713 MacCorkle Avenue, SE, Charleston, WV 25304*

After attending this presentation, attendees will better understand the forces and accelerations required to produce “whiplash” cervical soft tissue injuries.

The presentation will impact the forensic science community by quantifying a method to assess the potential for spinal soft tissue injuries based on the known scientific literature on the strength of the affected biological materials.

Over the years, there has been considerable argument over the occurrence of soft tissue injuries during low-speed collisions. Although a variety of ailments have been claimed during these low-speed impacts, only cervical soft tissue injuries are addressed in this presentation. Some of the most common unrelated injuries claimed include rotator cuff injuries, carpal tunnel injuries, Temporomandibular Joint Injuries (TMJ), Anterior Cruciate Ligament (ACL) injuries, and thoracic and lumbar spine injuries. Cervical soft tissue injuries are commonly referred to as “whiplash.” The range of complaints for this type of injury includes headaches, numbing and tingling of the arms, pain, and loss of range of motion.

In this presentation, the other types of injury claims are disregarded simply because they have no merit in low-speed rear-end collisions because a biomechanical effect cannot be attributed to them. Cause and effect must be established in order to proceed with biomechanical calculations. In this context, several researchers have studied the “whiplash” phenomenon. Clemens and Burrow determined that there are three areas of the spine susceptible to injury, at the base of the cranium and C1, the region of C3 and C4, and the region of C6 and C7. Their tests in the range of 17 miles per hour and decelerations of 30gs correlated to serious injury involving 90% of ruptures and 30% of fractures. They found that the limit of vulnerability to injury to be 13mph and 13gs. Damask places the vulnerability to injury between 13mph and 16mph and 13gs to 15gs to include isolated fissures of discs without injury to the ligaments or bones. The known scientific literature indicates a high probability of cervical soft tissue injury at accelerations of 17gs or greater.

From tests performed on biological materials, Yamada determined the lowest value of the ultimate strength of discs to vary from 0.20 Kg/mm² to 0.24Kg/mm². Calculations can be performed on the number of discs, a variation in the size of the disc structures, the weight of the individual affected, and various speed changes to determine the probability of injury to the cervical spine. This type of parametric analysis lends itself well to assess and correlate potential injuries to the work of other researchers that have established well-recognized limits on vulnerability to injury. Charts and graphs will be presented to show the analysis and the underlying basic equations used to formulate the problem.

Whiplash, Biomechanics, Spinal Injuries

Engineering Sciences Section - 2015

D13 Biomechanical Evaluation of Head Kinematics During Infant Shaking vs. Pediatric Activities of Daily Living

*John D. Lloyd, PhD**, 32824 Michigan Avenue, San Antonio, FL 33576; *William E. Lee III, PhD*, University of South Florida, College of Engineering, Tampa, FL 33620; and *Edward Willey, MD*, 7869 9th Avenue, S, Saint Petersburg, FL 33707

After attending this presentation, attendees will understand the mechanisms associated with traumatic brain injury in a pediatric population. Thresholds for injury will be discussed and compared against alleged forms of physical harm.

This presentation will impact the forensic science community by informing attendees that abusive shaking of infants has been asserted as a primary cause of subdural bleeding, cerebral edema, and retinal hemorrhages. This presentation seeks to compare linear and angular accelerations between infant shaking and pediatric activities of daily living.

Background: A biomechanical evaluation was performed to quantify kinematic variables associated with various infant shaking techniques, with comparison to a series of pediatric activities of daily living, as abusive shaking of infants has been asserted as a primary cause of subdural bleeding, cerebral edema, and retinal hemorrhages; however, manual shaking of various biofidelic mannequins has failed to generate the head kinematics believed necessary to cause these intracranial symptoms in the human infant. This study sought to compare linear and angular accelerations between infant shaking and pediatric activities of daily living. Additionally, injury risk as a function of known biomechanical thresholds of injury was determined.

Methods: Using InterSense^o sensors attached to the heads and torsos of two infant surrogates, investigators collected linear and angular motion data during resuscitative, aggressive, and gravity-assisted shaking as well as during various non-abusive activities normally experienced by infants, such as burping, rough play, etc. Tasks were performed by nine subjects, ranging in age from 20 years through 77 years and included two females and seven males. The researchers also collected data from a 7-month-old infant spontaneously at play in a commercial jumping toy. Raw data including orientation, angular velocity, and linear acceleration were acquired wirelessly. Using MATLAB[®], data was filtered by a 4th-order Butterworth low-pass filter. Angular accelerations were subsequently derived, root mean square values calculated and Head Injury Criterion (HIC15) computed. Results were compared between the experimental conditions, against other biomechanical studies of shaking, and in contrast to accepted biomechanical thresholds of injury.

Results: In these experiments, the peak rotational acceleration generated, averaged across nine adult subjects, during aggressive shaking of the Child Restraint and Airbag Interaction (CRABI) -12 biofidelic mannequin (1,068rad/s²) were both consistent with the reports of prior biomechanical studies and, most interestingly, statistically undifferentiated from angular accelerations spontaneously generated and well tolerated by a normal 7-month-old infant at play in a commercially available jumping toy (954rad/s²). Furthermore, measures of head angular acceleration are substantially below scientifically accepted biomechanical thresholds of injury. Thus, shaking produces head kinematics that are clearly benign and well tolerated by normal infants, even if repetitive. If intracranial injury (SDH, EDH, SAH, DAI, concussion) is clinically presented, this data would indicate that shaking would not be part of its etiology.

Conclusions: This is the first scientific study of the effects of shaking-related shear forces on a human infant brain and, of course, there were no ill effects experienced by the infant.

Non-contact shaking appears to result in head kinematics that are well tolerated by normal infants, even if these rotational accelerations are repetitive, as experienced by the infant at play. This data would indicate that intracranial injury in an infant is unlikely to be the direct result of the linear and/or angular accelerations generated during non-contact shaking.

Engineering Sciences Section - 2015

D14 Relationship of Risk Factors and Specific Tissues at Risk in Rear-Impact Collisions

*Scott D. Rosenquist**, 7620 Winding Oaks Drive, Colorado Springs, CO 80919; *Roger A. Russell*, Advanced Spine & Rehabilitation, 715 Mall Ring Circle, Ste 205, Henderson, NV 98014; *John J. Smith*, MSEE, PE, *Raymond P. Smith & Associates*, 43766 Buckskin Road, Parker, CO 80138; and *Bradley Boville*, BA, *Raymond P. Smith & Associates*, 43766 Buckskin Road, Parker, CO 80138

After attending this presentation, attendees will understand the most pertinent and valid risk factors associated with injury in motor vehicle occupants subjected to collinear rear-impact collisions. This presentation will address four common mechanisms which alter the biomechanical loading capacity of the cervical spine and one mechanism which is unique to rear impacts. For each mechanism, the presenters will describe what tissues or structures are placed at risk and how the pain of injury to these structures is expressed.

This presentation will impact the forensic science community by elucidating common factors which increase the risk of injury in rear-impact collisions. This will enable biomechanical experts to better understand and analyze the mechanisms of injury in these collisions and aid care providers in assigning prognoses to patients recovering from these events. This presentation will help illuminate a field which has been fraught with bias due to the lack of understanding of the true injury mechanism and interaction between human, vehicle, and collision factors which can increase injury risk and lower long-term prognosis for recovery.

The risk factors most commonly identified in motor vehicle collision testing include: (1) Gender — females are more likely to be injured in rear-end collisions than males.^{1,2} The female anatomy and physiology is less conducive to withstand impact loads, shear, compression, tension, torsion or jolt injuries as sustained in a rear-end collision; (2) Stature — persons with smaller frames and smaller neck circumferences are more likely to be injured in rear-end collisions.³ Tissues with smaller circumference or geometrical size are less able to withstand trauma; (3) Occupant Position — studies have found that when the head is rotated from ideal position, neck strain becomes more common.⁴ Additionally, multiple injuries and more severe injuries occurred with increased frequency.⁵ When an occupant is not seated in ideal position, structures are less likely to be in an optimal load tolerance state and likelihood of injury is increased; (4) Unpreparedness— it has been shown that unprepared occupants are more likely to sustain multiple injuries and more severe injuries.^{1,5} When an occupant is hit unaware, he or she is unable to brace for impact, which increases risk of deep spinal injuries and lowers prognosis for recovery; and, (5) Rear-Impact Unique Loading Event — when struck from the rear, a motor vehicle occupant experiences an S-shaped curve in the cervical spine, which produces a loading event unlike daily activities, sports, or other traumatic events.^{6,7} This event combines a pre-loading level of compression that decreases the load tolerance of the pain-sensitive structures of the upper quarter. This compression is immediately followed by a shear-torsion mechanism causing differential loading between the lower and upper cervical spine, concentrating forces and increasing the risk of injury of deep and superficial pain-sensitive spinal structures.

Forensic analysis and medical examination are further complicated by intrinsic links between these factors. For example, females are typically smaller than males and are more likely to have a smaller stature and automobile seats often do not accommodate persons of smaller stature, making it difficult or impossible for them to sit in ideal occupant position or brace effectively for collision. This presentation will discuss how the interplay of these factors affects likelihood of injury and prognosis for recovery of individuals involved in rear-impact collisions.

There is a confluence of evidence from international sources including independent and institutional researchers which consistently documents increased injury risk when these factors are present. This evidence comes from a variety of sources, including cadaver and human volunteer studies, autopsy studies, provocative injections, palliative injections, and long-term population studies. The data provided by each of these sources will be discussed as it relates to cervical injuries in rear-impact collisions.

D15 Biomechanical Evaluation of Shaking Impact Syndrome

John D. Lloyd, PhD, 32824 Michigan Avenue, San Antonio, FL 33576*

After attending this presentation, attendees will understand the risk of traumatic head and brain injuries in a pediatric population associated with shaking impact syndrome, a method often alleged in cases of abusive head trauma in young children.

This presentation will impact the forensic science community by informing attendees as to the mechanisms of head and brain injuries in pediatric populations and the risks associated with shaking and impact.

Introduction: A biomechanical evaluation of shaken impact syndrome was performed to evaluate the risk of injury to an infant. Injury risk was measured as a function of linear and angular head kinematics of a biofidelic infant surrogate during a biomechanical recreation.

Methods: Two adult males performed the shaken impact and impact activities. A Child Restraint and Airbag Interaction (CRABI)-12 biofidelic mannequin, height 0.75m and mass 10.0kg, was utilized as the infant surrogate. A 500G piezo-electric tri-axial accelerometer was installed at the Center of Mass (CoM) of the CRABI headform, in accordance with the Society of Automotive Engineers (SAE) J211 along with a tri-axial digital gyroscope.

A number of conditions were explored using a height-adjustable test apparatus. These included: non-contact shaking; shaken impact (which implies a brief shaking episode, followed immediately by impact); and, impact only. For the shaken impact and impact-only scenarios, participants were instructed to impart gentle, moderate, and vigorous impacts on the infant surrogate. In addition, the act of dropping the mannequin onto the surfaces was explored for the impact-only technique. Surfaces impacted included a standard infant crib mattress, a standard changing table pad with cover, and a hard wooden tabletop. Mattress height was set at a standard bed height of 23 inches, whereas the changing mattress and tabletop were both studied at 35 inches, as measured from the floor. Both participants performed five repeated trials for each condition, for a total of 230 trials.

Data from the analog linear accelerometer was acquired at 10,000Hz, per channel, using LabVIEW™ and filtered in MATLAB® using a phaseless 4th-order Butterworth filter with a 1650Hz cutoff frequency, per SAE J211. Data from the gyroscope was recorded at 5,585Hz, per channel, with no filtering necessary for this digital sensor. Head linear acceleration and angular velocities were recorded, angular acceleration was derived, peak magnitude values were calculated, and Head Injury Criterion (HIC15) computed.

Results: Findings indicate that angular accelerations associated with intentional impact and shaken impact are typically below infant brain injury thresholds of 8,000-10,000rad/s². The exception is vigorous impact against the changing pad or wood tabletop. It was also noted that dropping the infant surrogate onto the test surface produced injury risk similar to the moderate impact condition.

Conclusions: Across all events where sufficient rotational brain motion was recorded to produce significant brain injury, sufficient linear acceleration to cause skull fracture in an infant was also documented. Thus, considering the shaking impact or impact-only mechanisms, findings suggest that for there to be an underlying brain injury, a skull fracture is also likely.

Biomechanics, Pediatrics, Shaking Impact

D16 Can Barefoot Slip Resistance Be Quantified Using the ASTM F2508 Standard for Tribometric Testing?

Marcus P. Besser, PhD*, Pennsylvania State University Abington College, 1600 Woodland Road, Abington, PA 19001-3900; Mark I. Marpet, PhD, PE, 14 Cowie Road, Chester, NJ 07930-9715; and Howard P. Medoff, PhD, Pennsylvania State University, 1600 Woodland Road, Abington, PA 19001

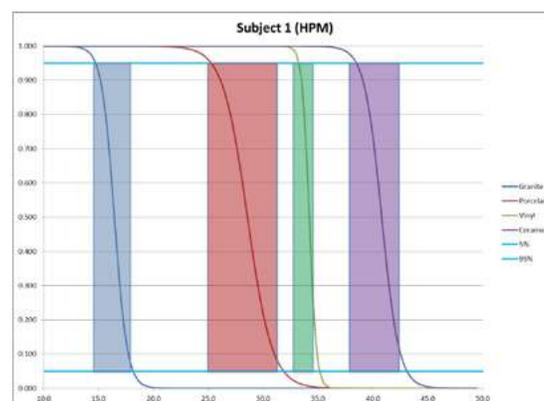

After attending this presentation, attendees will better understand the latest developments in barefoot walkway-safety tribometry.

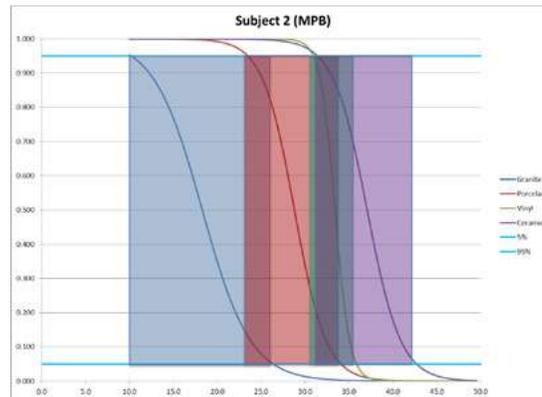

This presentation will impact the forensic science community by providing practitioners with an understanding of the problems and progress in barefoot tribometry and apprising researchers with an understanding of the state of barefoot tribometry.

Background: Walkway tribometers have been used to characterize slip resistance of walkway surfaces. Such tribometers typically use a Neolite® or leather “test foot” to assess slip resistance. This study explored barefoot slip resistance; while a leather or Neolite® Test Liner (NTL) test foot may resemble the outsole or heel of a shoe, it is a poor model for the human heel. In this experiment, a custom step meter was used to explore the behavior of the bare foot during slip, using the American Society for Testing and Materials (ASTM) F2508 *Standard Practice for Validation and Calibration of Walkway Tribometers Using Reference Surfaces* methodology.^{1,2}

The step meter is a device which can control the motion of the lower leg of an individual and allow the *in vivo* heel to be “dropped” onto a test surface in a repeatable manner. The test surface is inclined incrementally until slip occurs, similar to a “ramp test.” Previous studies have shown the step meter results to agree with those of validated tribometer tests.^{3,4} For this study, a more sophisticated statistical analysis than contained in F2508 is utilized: the logistic regression is used to find the point at which $p(\text{slip})=p(\text{no slip})=0.5$.⁵ A concurrent study validated the step meter fitted with an NTL test foot using the ASTM F2508 protocol.⁶ This study explores the behavior of the *in vivo* bare heel of two test subjects on the four reference surfaces used in the F2508 standard.

Experiment: There were two test subjects for this study. The testing procedure was as follows: prior to testing, the subject’s foot was allowed to hydrate for five minutes by submersion in a water bath. The subject’s right leg was then fixed in the step meter. The step meter allows the subject’s heel to be dropped vertically onto the test surface in a repeatable manner. The four reference surfaces described in ASTM F2508 were used in this study: granite (RS-A), porcelain (RS-B), vinyl (RS-C), and ceramic (RS-D). Surfaces were successively installed in the modified step meter and wetted with distilled water. For each surface, the instrument’s test-surface inclination angle was incrementally increased. At each angle, the heel was dropped onto the surface ten times and the number of slips occurring was recorded. A logistic regression was performed on the data to determine the $p(\text{slip})=0.5$ point and that value was recorded as the tribometer threshold for slip for that surface. The 5th and 95th percentile values were used as the lower and upper boundaries of the confidence interval for this measure.

Results: Graphs of the results of the logistic regression are shown above. For one subject, the combination of the modified step meter and the bare foot as test foot satisfied the F2508 standard. The results from the second subject, while similar to those of the first subject, did not statistically differentiate between the test surfaces.

Discussion: As the tribometer used in this study has been validated with a standard NTL Test Foot, one is left to speculate on the differences between the bare heels of the two test subjects evaluated.⁶ Why would one test foot “pass” F2508 and another not? It is suspected that there are differences between feet in a number of areas. Levels of hydration of the foot may have been different between the two subjects; no attempt was made to evaluate this hydration. There may be subject-to-subject differences in the skin ridges (heel “fingerprints”) that would affect slip resistance on a wetted surface; subject-to-subject differences may mean that some people have “slipperier feet” than others. While the reference surfaces were prepared as per F2508 (cleaning), no standard cleaning of the subjects’ feet was performed; it is possible that perspiration or other materials or factors “contaminated” the human test foot.

Further Research: The engineering solution to the problems discussed above would be to “standardize” the human foot for tribometric testing; however, if the objective is to assess the slip resistance of the barefoot pedestrian with any degree of biofidelity, such a test (or test protocol) *must* allow for subject-to-subject variations in the human heel. Such variation must be quantified to allow the application of tribometric walkway safety testing to the problem of barefoot walkway slip resistance.

McRoberts, BA, Reese, Lower, Patrick & Scott, Ltd, Architects, 1910 Harrington Drive, Lancaster, PA 17601; Tracy Morgan, MSc, Vancouver Coastal Health Authority, Corporate Office, 601 W Broadway, 11th Fl, Vancouver, BC V5Z 4C2, CANADA; and Craig Berger, BA, SEGD, 19 Hazel Avenue, Voorhees, NJ 08043*

After attending this presentation, attendees will: (1) understand the nature and extent of the needs of frail elderly adults in daily living; (2) be informed about the evidence base identifying gaps in toileting and bathing sections of the Americans with Disabilities Act (ADA) and American National Standards Institute (ANSI) Standards; (3) be informed of assisted-use supplements needed to meet ADA and ANSI Standards; (4) see research underway at the Georgia Institute of Technology's Center for Assistive Technology and Environmental Access and at IDEAS, Inc. where sufficient evidence does not exist regarding assisted use; and, (5) see a demonstrated example of the forensic process applied to creating new standards.

This presentation will impact the forensic science community by describing the work of a task force created to propose supplements to the 2010 ADA Standards for Accessible Design and the ANSI 2009 A117.1 Standard for Accessible and Useable Buildings and Facilities. For the purpose of this project, the Hulda B. and Maurice L. Rothschild Foundation partnered with the American Institute of Architects (AIA) Design for Aging Knowledge Community. This presentation was initiated by the Hulda B. and Maurice L. Rothschild Foundation, a national philanthropy focused on improving the quality of life for elders in nursing homes throughout the United States.

This task force is comprised of individuals committed to providing quality environments for *all* individuals, especially including frail elderly adults. Representatives include those of the foundation, architects, interior designers, researchers, providers, and others working collaboratively toward the goal of ensuring that standards which govern design of our environments provide for both safety and quality of life for *all* users. Since the ADA Accessibility Guidelines were initially issued in 1991, millions of Americans have benefited from changes to the built environment that provide greater opportunity and enhanced participation in society. Like most accessibility standards, they are intended to promote *independence*, generally based upon the stature, strength, and abilities of younger adults with a single disability, most of who transfer directly from wheelchair to toilet. In fact, much of the initial research utilized in development of the guidelines was based upon the physical challenges of returning veterans from the Vietnam War. These standards were developed around the capabilities of adults who: (1) have upper body strength; (2) can make sliding transfers; (3) have full cognition; and, (4) transfer independently.

Since the development of these early guidelines and standards, demographics of the population of people with disabilities have changed dramatically and now the limited functional abilities of the growing number of frail and elderly persons are not being adequately served by existing design standards as cited by the AIA Guidelines of 2002, which stated, "Hospital patients, and especially nursing facility residents, due to their stature, reach, and strength characteristics, typically require the assistance of caregivers during transfer maneuvers. Many prescriptive requirements of model accessibility standards place both elderly persons and caregivers at greater risk of injury than do facilities that would be considered non-compliant."

Initial phase of this project produced a white paper providing an evidence base and recommendations for *assistive* accessibility standards as supplements to the ADA and ANSI Standards to support and optimize functional abilities of frail elderly adults, reduce falls, and improve caregiver safety.

Recommendations for toilet room design are based on how frail elders transfer to the toilet with and without assistance and how space needs for staff and equipment must be accommodated. Changes in the bathing and showering area standards would provide *assistive* design options better enabling the person-centered care being mandated by the Centers for Medicare and Medicaid Services. Further, the proposed changes are consistent with the intent of 2002 AIA Guidelines that called attention to the disparity between accessibility standards and the needs of older adults and their caregivers.

Engineering Sciences Section - 2015

Forensically, adoption of supplementary guidelines and standards for residential care environments will reduce ambiguously based law suits regarding personal injury from falls for frail elders and back injuries to caregivers. Jurisdictional authorities will be able to make more informed decisions about accessible design for frail elders in assisted living and nursing home communities. Forensic expert architects, specialized in ADA and ANSI compliance will have strong bases upon which to investigate, report, and testify in court.

This presentation will conclude with a description of research progress and an example of successful forensic endeavor.

Frail Elderly, Assisted, Standards

Engineering Sciences Section - 2015

D18 Evaluating the Impact of Reroofing on Increasing the Risks of Ponding of Water

Daniel M. Honig, PE, Structures Consulting Engineer, PO Box 125, Swarthmore, PA 19081*

After attending this presentation, attendees will understand some factors that affected and contributed to a roof ponding event, as well as how the selected materials, installation procedure, and localized drainage conditions caused the collapse of a recreational facility roof.

This presentation will impact the forensic science community by using a case study to illustrate how modification work done on a building can negatively impact the structural integrity of that building. This presentation also highlights the importance of building code compliance, which often prevents building collapses as building modifications are made over time.

Ponding, the unexpected pooling of water, often occurs with catastrophic events and is a predictable condition in areas of heavy rainfall. The weight of rapidly congregating water on a rooftop can cause an existing structural roof system to deflect and progressively collapse during intense rainstorms.

In this instance, reroofing work completed on a recreational facility negatively altered the roof drainage capability of the building. The continuing adequacy of the rooftop drainage system was not properly reevaluated as part of the reroofing project, thereby leading to a significant structural roof failure incident approximately a year later during a rainstorm microburst. In this case, a localized portion of the structural steel support system of the roof collapsed due to ponding from a blockage created in the drainage system.

Prior to this ponding incident, the original roof drainage system had functioned properly for more than 20 years since the time it was constructed.

The major factor contributing to the ponding failure was the installation of two-inch-diameter drain inlets without proper debris-protection baskets during the reroofing process. The thickness of the drain inlets and the installation of an Ethylene Propylene Diene Terpolymer (EPDM) membrane within the inlets reduced the effective drainage diameter to approximately the size of a common bathtub or shower drain. This reduction in diameter significantly and proportionally reduced the effective drainage area of the roof drainage system by as much as 80%. In addition, no secondary or overflow roof drainage system was provided as per code. The new roofing material installed, including flute fillers and insulation, also created additional dead loads to be supported by the existing structural roof framing members.

While the roofing design of the original building would not have required emergency scuppers, the drainage system was altered, thereby making it inadequate to withstand even regular rainfall events. The significant drainage capacity reduction, in combination with the lack of protection baskets and the potential for blockage of the inlets, allowed the significant roof ponding and additional roof loading to occur. In this case, the reroofing contractor did not conduct a proper engineering review of the rooftop surface conditions as part of the completion of the reroofing job. While plumbing codes prohibit the reduction of drainage diameters on existing buildings, appropriate attention by installers to the impact of modification work on the structural integrity of a building could also help prevent such failures in the future.

Ponding, Roof Collapse, Reroofing

Engineering Sciences Section - 2015

D19 A Test Program to Validate a Step Meter Using Neolite® Test Liner (NTL) as a Test Foot per the ASTM F-2508 Protocol

Mark I. Marpet, PhD, PE, 14 Cowie Road, Chester, NJ 07930-9715; Marcus P. Besser, PhD, Pennsylvania State University Abington College, 1600 Woodland Road, Abington, PA 19001-3900; and Howard P. Medoff, PhD*, Pennsylvania State University, 1600 Woodland Road, Abington, PA 19001

After attending this presentation, attendees will understand the steps needed to validate a new tribometer under the American Society for Testing and Materials (ASTM) F2508.

This presentation will impact the forensic science community by showing how tribometer validation, important under the *Daubert* and *Frye* court decisions, can be accomplished.

ASTM committee F13 (Pedestrian/Walkway Safety and Footwear and Walkway Safety) is charged with developing standards and procedures to increase pedestrian-ambulation safety. “A primary focus of the Committee is the measurement of slip resistance” (ASTM F13). To that end, over the years, this committee has approved specific tribometers (devices to measure on-site slip resistance between flooring and shoe bottoms) (e.g., ASTM F1677 — Portable Inclined Articulated Strut Slip Tester, ASTM F1678 Portable Articulated Strut Slip Tester, and ASTM F1679 — Using a Variable Incidence Tribometer). A number of years ago, each of these standards were withdrawn from active development, mainly because these standards referenced proprietary instruments. Replacing them was a non-proprietary standard (ASTM F2508 — Standard Practice for Validation, Calibration, and Certification of Walkway Tribometers Using Reference Surfaces) to verify the ability of a tribometer to measure the slip resistance (between the floor and test foot.) This standard included four reference surfaces: black granite, porcelain tile, vinyl composition tile, and ceramic tile (with an increasing slip resistance in the referenced order). Essentially, if a tribometer’s test results were ordinally correct (with the test results in same order as the reference surfaces as listed above) and statistically discriminated, the tribometer was “validated” as per ASTM F2508.

Preliminary Studies: (1) In a previous study, a step meter (variable inclinable) was developed to compare slip-resistance results of a test subject and a tribometer.¹ The device is similar to a ramp test, except the test subject stood in the device and stepped down (successively) on a test surface that had its inclination increased until a slip occurred. The test results were comparable between the step meter and a Portable Inclined Articulated-Strut Tribometer (PIAST); and, (2) In a later study, the step meter was modified to allow the test subject to remain seated.² The test subject’s leg was raised and dropped on a test surface that had its inclination increased until a slip occurred. The leg was constrained to move vertically. This seated configuration for the test subject (as compared to standing) was found to have increased reliability as shown by a steeper logistic-regression curve.

The Current Experiment: The goal is to verify that the step meter equipped with a grooved Neolite[®] Test Liner (NTL) test foot will pass validation under the ASTM F2508 protocol. This same NTL test foot, when used in a PIAST, had been found to meet the ASTM F2508 criteria. The hypothesis is that the step meter-measured available friction will result in these reference surfaces being “placed” in the rank order (section 9.2.1, ASTM F2508) and the differentiation between these surfaces will be statistically different (section 9.2.2, ASTM F2508).

In order to validate (as per ASTM F2508) the seated step meter, it was equipped with an articulated tribometer strut (hinged at the top and dropping vertically) with a grooved NTL test foot, contacting water-wet ASTM F 508 reference surfaces. The surfaces (resting on a bottom plate) could be rotated, changing the orientation between the grooved NTL test foot and these surfaces. The reference surfaces were bathed in a continuous film of water supplied by a recirculating pump. (Triton[™] X-100 was not used as a wetting agent on the black granite surface as the test surface was continuously bathed in the water.) The NTL test foot was dropped onto the reference surfaces successively (with the reference surfaces initially horizontal). The reference surface was rotated toward the vertical in small increments until slip occurred.

Figure 2: The Modified (Hybrid) Step Meter.

The articulated strut moves vertically down onto the test surface. The test foot (grooved NTL) is attached to the strut by means of a clip. Water is continuously sprayed onto the test surface by means of PVC drilled tubes (on either side of test surface). The test surface rests on a flat surface (shown in photo). The test surface is “tilted” to provide any angle between the vertical strut and the test surface. The strut “drops” onto an angled, water-wet test surface. When slip occurs, the angle of the test surface is measured.

The testing was conducted as per the ASTM F2508 protocol (10 tests in each of four perpendicular directions). The angle of the reference surface was measured and recorded when the test foot slipped. The results were statistically analyzed as per ASTM F2508.

The results show that this modified step meter, using the ASTM F2508 reference surfaces, was able to differentiate the slip resistance of these surfaces in the proper order, and met the F 2508 criteria for validation of a tribometer.

D20 Anomalous Initial Readings in Tribometric Testing of Barefoot Subjects

Mark I. Marpet, PhD, PE*, 14 Cowie Road, Chester, NJ 07930-9715; Marcus P. Besser, PhD, Pennsylvania State University Abington College, 1600 Woodland Road, Abington, PA 19001-3900; and Howard P. Medoff, PhD, Pennsylvania State University, 1600 Woodland Road, Abington, PA 19001

After attending this presentation, attendees will be familiar with certain problems that appear in walkway-safety tribometry and how to statistically test for the presence of these problems.

This presentation will impact the forensic science community by alerting practitioners to potential problems in tribometric testing, how to determine if such problems exist, and how to eliminate them.

Background: A modified Stepmeter is in the process of being validated under ASTM F2508 Standard Practice for Validation and Calibration of Walkway Tribometers Using Reference Surfaces.¹ Briefly, the Step Meter is a cyborg-like take-off of a Slip-Test Mark II Portable Inclinable Articulated Tribometer, where a human subject's leg is constrained to move only vertically and/or rotate forward from the knee joint. The subject's constrained leg is passively lowered against an inclined test surface.² More sophisticated statistical analysis than contained in F2508 is utilized, viz., logistic regression is used to find the point at which $p(\text{slip}) = p(\text{no slip}) = 0.5$.³ In the validation process, repeated tests (foot lowerings) are conducted at a given test-surface inclination angle and the sequence of slips versus no-slips is recorded. A visual inspection of the data raised the hypothesis that the initial foot lowerings in any sequence of same-angle tests appears to be somehow different from the rest of the sequence.

Experiment: To investigate this hypothesis, Official Vinyl Composition Tile (OVCT, Reference Surface C in F2508) and then Ceramic Tile (Reference Surface D) were successively installed in the modified Step Meter. The instrument's test-surface inclination angle was adjusted for each test surface so that the $p(\text{slip})$ was approximately 0.5. For each surface, repeated series of ten foot-lowerings were conducted (11 sequences for the OVCT and 10 for the Ceramic Tile). The slip/no-slip results were recorded in sequence (i.e., slip, slip, no-slip, ..., slip). The number of slips was histogrammatically tabulated. If the probability of a slip is constant from foot lowering to foot lowering, the probability of the first slip at the k th trial will follow a geometric distribution:

$g(k; p) = p(1 - p)^{k-1}$; $k = 1, 2, \dots, 10$ and $0 \leq p \leq 1$ where $p = \frac{\text{number of slips}}{\text{number of trials}}$. For example, this study observed in total 53 slips in 110 trials for the OVCT, thus $p = \frac{53}{110} = 0.482$. A χ^2 goodness-of-fit test was conducted, where the expected number of occurrences was compared with the observed number of occurrences: (1) H_0 : Distribution cannot be distinguished from

a Geometric Distribution; (2) H_1 : Distribution doesn't follow a Geometric Distribution; (3) Test Statistic: $\chi^2_{\text{test}} = \sum_{k=1}^{11} \frac{(O_k - E_k)^2}{E_k}$

with $k-2$ degrees of freedom, and, (4) Where $E_k = 11g(k; 0.482)$.

First slip=k	$g(k; 0.482)$	$E_k = \text{Expected}$	$O_k = \text{Observed}$	$(O_k - E_k)^2 / E_k$
1	0.482	5.30	1	3.4887

11	0.001	0.01	0	0.0074
Totals->	1.0	10.98	11.00	$\chi^2 = 67.20$

Engineering Sciences Section - 2015

The p -value (i.e., $P(X \geq 67.20)) = 0.0$. That is, the probability that, under a geometric distribution, one could achieve the X^2 result found would be effectively zero: effectively an impossibility. For context, the 1% critical value is $\chi^2 = 21.7$.

The first and then the first and second foot drop results were then removed from the calculation. With the first reading in the sequence dropped, $\chi^2(8 \text{ d.f.}) = 31.4$, with corresponding p -value of 0.0001, still highly significant. With the first and second readings in the sequence dropped, $\chi^2(7 \text{ d.f.}) = 11.89$, corresponding to a p -value of about 10%, which is conventionally considered not significant. That is, with the first and second readings in each sequence ignored, the data could not be distinguished from a geometric distribution.

For the ceramic tile, $\chi^2(8 \text{ d.f.}) = 31.1$, with a corresponding p -value of 0.0001. With the first foot-dropping result eliminated, $\chi^2(7 \text{ d.f.}) = 12.17$, with a p -value of about 10%: not considered to be significant. With the first two foot-dropping results eliminated, $\chi^2(6 \text{ d.f.}) = 2.17$, with a p -value of about 90%. (If you believed the results didn't follow a geometric distribution, you would have an approximately 90% chance of being *incorrect*.)

Recommendations: On the basis of these results, it would preliminarily be recommended that, at least for barefoot tribometry, the first two readings in any set of tests be ignored. That is, one should not record the first two test-foot drops. This study suggests that at least one of those two test-leg drops should be a slip.

Further Research: This study intends to extend this experiment to the other two ASTM Reference Surfaces (Granite and Porcelanosa Ferrocker, A and B respectively). More important, perhaps, is to extend this work to testing using a Neolite® Test Liner Test Foot, a commonly used surrogate for a shoe heel. There are anecdotal reports of the same anomalous behavior in NTL tests, and thus bears investigation.

D21 Forensic Investigation of a Premature Mortar Explosion That Resulted in the Death and Maiming of Several United States Marines

John Nixon, MBA, ARC, PO Box 66, Bippus, IN 46713*

After attending this presentation, attendees will understand how a mortar system is designed and works and what can go wrong. Additionally, attendees will learn how defects can be identified post-accident using deductive reasoning, the importance of correct designation, and the use of fact vs. expert witnesses.

This presentation will impact the forensic science community by establishing that deductive-reasoning analytical techniques may be gainfully employed outside their typical use in medical diagnoses. This presentation will also highlight the importance of correctly designating expert and fact witnesses.

This presentation will educate attendees as to potential failure modes in medium caliber mortar systems, civil litigation fact/expert witness procedure pitfalls, and illustrate the legitimate use of deductive reasoning to form scientifically valid conclusions in instances where much of the physical evidence is lost or destroyed.

This presentation focuses on an actual forensic case study relating to a training accident involving United States marines who were conducting a training exercise using a battery of medium caliber mortars. The case is interesting for a number of reasons. First, mortar system failures are very rare. Second, the use of deductive reasoning, while widely accepted in the medical profession when making diagnoses, may be frowned upon outside of the medical profession; however, in this instance, the court ruled that the technique was appropriate to utilize in a situation where the majority of the evidence was destroyed and/or lost. Third, the case demonstrated, from a legal perspective, the importance of correct identification and use of fact versus expert witnesses and the perils of flouting relevant correct procedures.

Medium caliber mortar systems are the heaviest portable artillery that may realistically be carried by infantry troops. A mortar is the most basic form of artillery, but is nonetheless a very valuable weapon system that provides a tactical edge to infantry during forward operations. The mortar system is comprised of a muzzle-loading smooth bore gun (tube) and fin-stabilized high-explosive projectiles with an integral propelling charge system. The gun itself is comprised of a barrel, a base plate, and an aiming system. The firing pin is fixed, at the bottom of the tube, and the ammunition propelling charge is ignited by a percussion primer that impacts the firing pin when the ammunition is dropped down the tube by the loader. It is a low-pressure, low-stress system, and this enables the tube weight to be kept to a minimum, thereby ensuring that the system is man portable.

If all goes according to plan, the crew sets up the mortar and sets the tube to the correct angle of elevation to achieve the range they need using the propelling charge they have selected. The loader drops a round of ammunition, fitted with the appropriate number of propelling charge segments, into the muzzle end of the tube. Gravity takes the round of ammunition to the bottom of the tube at which point the percussion-actuated primer makes contact with the fixed firing pin and the propelling charge is initiated. The round of ammunition is accelerated up the barrel (tube) and makes its way to the target. The ammunition incorporates a safety and arming device in the nose-mounted fusing system. This safety and arming device ensures that the high-explosive charge in the warhead cannot be detonated by the fuse/booster while the round is still in the tube or while it is within an unsafe distance of the gun emplacement.

These mortar systems are comparatively simple, safe, and reliable. The gun tube is inspected regularly and the degree of wear noted. At some point, the tube will fall below the minimum safe-wall thickness, exhibit signs of cracking, and be replaced. There are several things that can potentially go wrong and result in crew injuries or fatalities. In broad terms, these fall into three main categories: (1) the tube may rupture due to excessive wear and/or metallurgical defects (tube failure); (2) the ammunition warhead may detonate prematurely due to body failure, fuse failure, or high-explosive warhead defects; or, (3) the crew may insert a live round into the tube before the previous one has left (double charge=operator error). Any of these events are bad news for the crew who are, by necessity, in very close proximity to the tube. A tube failure is less catastrophic than a premature detonation of the high-explosive warhead. A double charge may result in the two rounds of ammunition being propelled harmlessly downrange, or a very violent in-bore explosion. The case under review was further complicated due to issues relating to evidence examination (resolved pre-trial) and designation and use of expert vs. fact witnesses (resolved on appeal).

Mortar Accident, Deductive Reasoning, Expert vs. Fact Witnesses

D22 Catastrophic Failures in Firearms and Ammunition Attributed to Propellant Issues, Metal Fatigue, High Pressure, Incorrect Ammunition, and Other Factors

Ronald R. Scott, MA, MS, 37881 N 10th Street, Phoenix, AZ 85086*

The goal of this presentation is to provide an understanding and appreciation of the multiple issues and conditions which can produce a dangerous potential for firearms and ammunition to become unintended explosive devices which often results in catastrophic failure and consequential degrees of property damage and serious personal injury including death.

This presentation will impact the forensic science community by informing attendees that these explosive incidents can occur with perfectly safe and fully functional weapons that have not previously shown any signs of an impending problem. Inadvertent lapses in quality control during the manufacturing processes may permit substandard products to enter the market with this fact becoming apparent only after a catastrophic incident.

Injuries from firearm malfunctions are mostly preventable through common safe practices including the use of protective equipment, routine maintenance and inspection, and being aware of the typical symptoms and signs which precede a catastrophic failure; however, even a proactive approach will not uncover the hidden dangers.

Firearms and ammunition are dangerous weapons which have been designed for a variety of purposes. The average shooter will not encounter any significant or serious problem over their lifetime while engaging in the use of firearms. Despite the warnings and practices that are learned in common safety education programs, there are circumstances which can develop through no fault of the shooter that results in the firearm becoming a pseudo pipe bomb resulting in its spontaneous disassembly and fragmentation.

The typical injuries suffered during these explosive events involve the hands and face. Forensic investigations into these incidents are not commonly conducted by personnel in crime laboratories since the personnel are usually restricted to basic firearms testing for functional design and the identification of evidence; they are most often analyzed by engineers or other specialized consultants who have backgrounds in firearms and ammunition design and who have studied the causes and effects of blast damage.

Over the last several years, the civilian shooting environment has seen an influx of very large caliber weapons that were restricted to the military. This presentation will discuss some specific areas of catastrophic failure which result from the use of incorrect ammunition, metal fatigue, plugged barrels, high- and low-pressure detonation, improper assembly, use of the wrong type of propellant including how burning rates affect the movement of projectiles in the barrel, and discuss the correspondence of peak pressures in relation to barrel length.

Firearms, Catastrophic Failure, Injuries

D23 Injuries Arising From Glass Drinking Vessels Used in Stabbing and Slashing Attacks

*Sarah V. Hainsworth, PhD**, University of Leicester, Dept of Engineering, Leicester LE1 7RH, UNITED KINGDOM; *Ryan Pitchford, BS*, University of Leicester, University Road, Leicester LE1 7RH, UNITED KINGDOM; *Richard W. Earp*, University of Leicester, Dept of Engineering, University Road, Leicester, Leicestershire LE1 7RH, UNITED KINGDOM; *Stuart J. Hamilton, MB*, Leicester Royal Infirmary, East Midlands Forensic Pathology Unit, Level 3, Robert Kilpatrick Bldg, Leicester, Leicestershire LE2 7LX, UNITED KINGDOM; and *Guy N. Ratty, MD*, University of Leicester, Forensic Pathology Unit, Robert Kilpatrick Bldg, Leicester LE2 7LX, UNITED KINGDOM

The goal of this presentation is to show how breakage of glass pints used in stabbing and slashing attacks can cause injury and the typical forces that are generated by an attack with a glass drinking vessel.

This presentation will impact the forensic science community by assisting forensic engineers and other professionals who need to interpret glass injuries to understand the forces generated and the way in which the glass fracture and fragmentation leads to injury.

Recent reports in the United Kingdom estimate the annual cost to the National Healthcare System as a result of alcohol harm at £2.7bn. Glassware is used as an impulsive weapon in 4% of violent incidents in the United Kingdom. The injuries that occur can be significant, leading to serious injury and death and usually fall into categories of either stabbing or slashing. Injuries can also have a component of blunt force trauma depending on the way in which the weapon is used. In order to better understand the injury potential of different types of glassware and measure the forces involved in glass-related attacks, a study has been conducted using English pint glasses, in particular “Nonic” glasses and “Tulip” glasses. Slapping attacks, where a glass is held in the hand and slapped onto the victim, are dynamic attacks and in order to determine the level of force that can be generated, a novel force-plate dynamometer was used to record the peak forces generated by a number of assailants. A typical example of the force-time data is shown in Figure 1. The peak force generated in this instance was 1,208N. The further peaks arise from the dynamic oscillations (vibrations) induced in the dynamometer by the initial impact. The force generated is considerable and easily sufficient to penetrate skin with a glass fragment from the fracture of the glass on impact.

Additionally, high-speed video was used to record the way in which the glasses fractured and any shards from the glasses penetrated a synthetic skin simulant. Tests were made onto both a flat plate and a mannequin head. A silicone rubber skin simulant was used to allow the damage created by shards to be assessed. Annealed and tempered glassware was tested and the glass fracture patterns and types of shards that are generated were compared in terms of the damage that was obtained. The average force generated during a slapping attack was found to be ~1,000N. This is a significant force and therefore it would be expected that the injuries would be a combination of blunt force injuries and sharp force injuries from the glass fragments that result on impact. The results of the engineering experiments are presented in terms of observed forces and damage patterns and compared to those found in a pathology context in order to gain an improved insight into the way in which injuries arise in assaults using glass as an impulsive weapon.

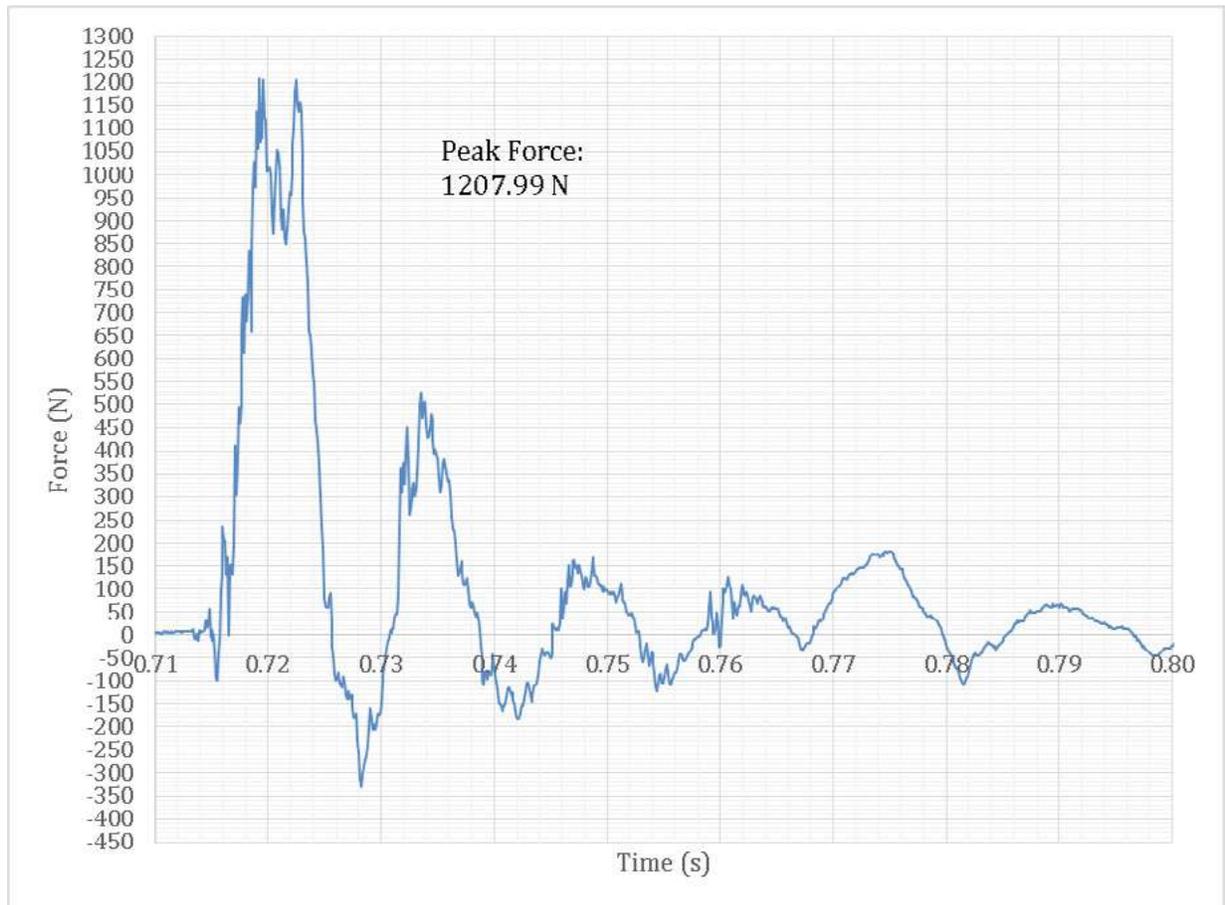

Figure 1: A force-versus-time graph for a slap with a “Tulip” geometry glass

Glass, Glassing, Fracture

Engineering Sciences Section - 2015

D24 Investigation of “Inert” Artillery Shell Explosions

John Nixon, MBA, ARC, PO Box 66, Bippus, IN 46713*

The goal of this presentation is to demonstrate the importance of ensuring that staff have a responsible disposition and that they are appropriately qualified and trained to deal with the hazardous materials likely to be encountered during munitions decommissioning operations.

The presentation will impact the forensic science community by highlighting the importance of repeated safety inspections, even when multiple levels of paperwork indicate that a proposed operation will be safe to perform.

The case involved the decommissioning and recycling of military munitions that had been in storage and had exceeded their specified service life. Decommissioning of live explosive munitions is a delicate, potentially dangerous, and expensive process. The usual procedure is to inert the munitions by removing fusing and explosive warhead materials, then ship the remaining inert components to scrap metal processors for final disassembly and metals recycling.

Military authorities typically follow one of two courses of action for inerting the munitions. They can have a government/military entity perform the inerting process or they can have an approved private contractor do it. Needless to say, it is important that each step of the process be carefully monitored and documented to ensure that no munitions, removed fusing components, or energetic warhead materials are mishandled, misplaced, or lost to potentially dangerous criminals/terrorists.

Once the residual munitions components are certified as inert, they can be sold to scrap metals processors for final disassembly, destructive breakdown, and sale to metals smelters/recyclers. In recent years, some insurance companies have insisted that recycling processors not accept decommissioned munitions for processing, presumably because of the perceived high risk.

In this case, the empty shells were sold and transported to a large scrap metals processor who deemed it necessary to cut the shells into smaller parts. This cutting was to be accomplished using dual gas cutting torch equipment. Unfortunately, one or more of the shell bodies contained a significant amount of high explosive and a young contract employee was fatally injured when he took a cutting torch to a steel shell body and the high explosive detonated. Warning signs were not recognized and/or ignored. The young worker lost multiple body parts and faculties and took several weeks to die. The subsequent litigation investigation uncovered numerous alleged errors and lack of care issues on the part of the scrap metals processing plant and the employee's family were given substantial financial damages for the death and suffering of their family member. As with many investigations, this one revealed some interesting issues with both plant procedures and supervisors.

Artillery Shell, Munitions Decommissioning, Explosives Fatalities

D25 Killing-Power Ranking of Blunt Instruments — Establishment of a Method to Evaluate Human Injury

*Shohei Daimaru**, 4-3-11 Takeda, Kofu-shi, Yamanashi-ken 400-0001, JAPAN; *Yasumi Ito*, PhD, Furo-cho, Chikusa-ku, Nagoya, Aichi 464-8603, JAPAN; *Yoshiyuki Kagiya*, PhD, University of Yamanashi, 4-3-11 Takeda, Kofu-shi 400-0001, JAPAN; *Ryotaro Kishida*, University of Yamanashi, 4-3-11, Takeda, Kofu-shi, Yamanashi Prefecture 400-8511, JAPAN; and *Kohei Fujigaya*, University of Yamanashi, 4-3-11 Takeda, Kofu-shi 400-0001, JAPAN

After attending this presentation, attendees will understand the relationship between impact velocity and maximum impact force by typical blunt instruments in order to determine a technique for quantification of impact force

This presentation will impact the forensic science community by determining the existence or non-existence of murderous intent for a criminal trial.

In a murder case and accident, evaluation of human injury was conducted at the same time as a postmortem examination and investigation. It is difficult to quantify when the size of impact force from human injury is evaluated. There are many parameters presented in this study, such as acting force, maximum force, and acting time. Then, in the case of bone fracture-risk evaluation by blunt instrument, the circumstances of a murder case and accident can be explained. According to an on-the-spot investigation report and recording of a statement, it's possible to perceive the circumstances of a murder case and accident.

This study investigates and analyzes the following: (1) estimation and selection of impact position by blunt instrument; (2) impact force that an assailant can show (physical or environmental factor); (3) the case of situation which a sufferer receives (a back or a wall); and, (4) choice of injury parts.

The results of the analysis were carefully examined. Then, the condition of impact force-measuring experiment was set and the impact experiment was conducted by the same or similar blunt instrument compared to the actual weapon. In a murder case and accident, the range $F_{min} \sim F_{max}$ of impact force F were narrowed. Furthermore, as a result of the examination, bone fracture limits force f of the sufferer was presumed. Last, impact force F and bone fracture limit force f were compared: $F_{min} > f =$ bone fracture risk low; $F_{min} < f < F_{max} =$ there is the possibility of the bone fracture; $F_{max} < f =$ bone fracture risk high. Judging from this, a test result is assumed.

Using a variety of blunt instruments, the following three experiments were performed: (1) a difference in impact force of impact position by blunt instrument; (2) measuring of down swing velocity from an individual difference; (3) an impact experiment concerning artificial human soft tissue.

As a result of the experiments, the following were suggested: (1) it was found that down velocity by blunt instrument was so fast as to be below the impact position; (2) because of material and impact velocity, it was clear that the tendency is to decrease load from a position which is measured maximum force to the tip; (3) there were good relationships between impact velocity and maximum impact force using a modeled skull made of formed styrol; and, (4) the blunt instrument confirmed that it's possible to estimate the maximum impact force the skull receives from impact velocity.

Human Injury, Human Soft Tissue, Impact Velocity

D26 A Study of Batch-to-Batch Handgun Ammunition Propellant Variables and Their Influence on Muzzle-to-Target Distance Determinations

John Nixon, MBA, ARC, PO Box 66, Bippus, IN 46713*

After attending this presentation, attendees will understand ammunition construction and the variables in propellant composition and morphology that exist between different batches of externally identical ammunition. The impact of these variables on the validity of muzzle-to-target distance determinations will be discussed.

This presentation will impact the forensic science community by affecting the way in which muzzle-to-target distance determinations are performed when a sufficient quantity of identical ammunition is not recovered.

Deceased gunshot wound victims frequently have close range wounds to bare skin that exhibit sooting and/or stippling, to varying degrees. It is common practice for technicians to perform muzzle-to-target distance determinations using the same brand and, when known, loading of ammunition. This presentation illustrates and discusses the variability of propellants (especially propellant geometry/morphology) discovered within different lots of the same brand and loading of premium ammunition. The variability in combustion, stippling, and sooting characteristics were studied in the context of their impact upon the accuracy and validity of muzzle-to-target distance determinations that are based upon these visual indicators. The results and conclusions of the study will impact the way that muzzle-to-target distance determinations are performed when a sufficient quantity of identical ammunition is not recovered.

The degree of sooting, and the maximum range for sooting, vary significantly depending upon the propellant used in the subject ammunition. Typically, propellants manufactured with a greater variety and/or quantity of additives will produce more sooting. For most handgun/ammunition combinations, visible sooting will cease at a muzzle-to-target distance of approximately nine to twelve inches, but it is not uncommon for some “dirtier” ammunition types to leave visible soot deposits out to fifteen inches or more.

Additionally, old propellants or propellants that have prematurely aged due to being inappropriately stored (high temperatures and/or repeated temperature cycling — such as may be encountered in a vehicle, for example) typically produce a greater degree of both sooting and stippling than would otherwise be the case. It is generally accepted that stippling from a handgun will cease at a maximum muzzle-to-target distance of approximately three feet. Occasionally, stippling may occur beyond that three-foot limit, but it is more usual for stippling to cease at a muzzle-to-target distance of approximately two feet; however, the propellant characteristics that most influence maximum range and dispersion of stippling are propellant grain mass, size, and morphology. Propellants used in handgun ammunition typically fall into one of three morphology categories — ball, flake/disk, and cylindrical. It is not uncommon for propellants to be blended, and thereby be comprised of more than one propellant grain geometry type. Clearly, there are implications for the aerodynamic characteristics for each of the three propellant grain geometries cited — a grain of ball propellant will travel further than a grain of flake propellant, for example.

The research conducted for this presentation focused on a practical study of several batches of the same loading of premium defensive handgun ammunition that had been manufactured by a long-established and reputable manufacturer. Disassembly of samples from the different batches revealed that different propellants had been utilized — the primary concern of the manufacturer being to achieve the same batch-to-batch average muzzle velocity, without regard for propellant type. The differing propellants encountered in each batch may have had varying additive content (in terms of both composition and quantity). The propellants were primarily identified and classified merely by their size and morphology. The primary purpose of the research was to investigate the variation in sooting and stippling characteristics between different batches of ammunition of the same brand and loading, given the knowledge that the propellants used differed significantly from batch to batch. The research demonstrated that sooting and stippling characteristics varied widely between different batches of the same brand and loading of ammunition, due to the varying size and morphology of propellant grains used during manufacture. Consequently, it was concluded that a technician who tested for muzzle-to-target distance using a given brand and loading of ammunition, assuming that the results would be representative, may obtain erroneous muzzle-to-target distance results if the ammunition batch were not identical. Current laboratory protocols and generally accepted practices do not consider these ammunition variables.

Engineering Sciences Section - 2015

If a significant quantity of ammunition is recovered for testing, the previously cited problems will be of little concern, assuming a visual examination of propellant samples confirms that it is all identical; however, in cases where only one round or a limited quantity of ammunition is available, it is recommended that it be dismantled and new ammunition procured for testing. The propellant from the new batch(es) of ammunition should be compared to the case sample to ensure propellant similarity and thereby guarantee the validity of any subsequent muzzle-to-target distance determinations.

Propellant Morphology, Propellant Stippling, Distance Determinations

Engineering Sciences Section - 2015

D27 Testing of Police Radar

Mark E. Goodson, PE*, 1500 Spencer Road, Denton, TX 76205-5105; and Gary Hartzler, BSME, Goodson Engineering, 1500 Spencer Road, Denton, TX 76205

The goal of this presentation is to improve attendees' understanding of the limitations of police radar, as well as to impart how it is technically implemented in both software and hardware. The outcome will show that improvements in electronics techniques have resulted in radar systems that ignore some reflected target signals by treating them as "noise," when in fact they are signals from valid vehicles. Attendees will also see that displayed speeds are not displayed in a way that correlates with an officer's discernment of traffic.

This presentation will impact the forensic science community by demonstrating that although police radar is used for enhancing traffic safety, it is also used for enhancing governmental revenue, as well as serving as the basis for traffic stops in which law enforcement then searches a vehicle for contraband. Such law enforcement techniques are appropriate when the basis for executing a traffic stop are lawful. This presentation demonstrates that traffic radar is not reliable when subjected to *Daubert* criterion in that it leaves too much discretion to the officer. In that it is not reliable, its use as a basis for searches of vehicles and resultant convictions due to the carrying of contraband (drugs, weapons) raises 4th-amendment questions. The outcome of this research is that there may be post-conviction relief for citizens who were righteously convicted for contraband offenses after being searched without the necessary probable cause.

Police radar forms the mainstay of many police department traffic enforcement programs. While enforcement of traffic laws is within the purview of a police department or state police group, anecdotal experience has shown that the issuance of citations for speeding is sometimes done to enhance governmental coffers. In that speeding tickets represent the most frequent brush with the law that many citizens have, one would think that police radar is a highly sophisticated tool that leaves the operator no discretion in determining the speed of a vehicle.

The reality of police radar is that it fails when subjected to the *Daubert* test. In this regard, police radar operation *should* be repeatable — this research demonstrates that it is not a repeatable technique and is, in fact, subject to operator interpretation when multiple targets are present.

The research utilized several brands and models of radar units, operating simultaneously. When one target was present, the radars were usually within tolerance of one another; however, when multiple targets are present, there is no guarantee as to which vehicle's speed will be displayed — the radar units can well read different speeds, leaving interpretation up to the operator. It is demonstrated with these units that the decision to issue a citation is highly dependent upon the operator, relative to the instrument.

Radar can pick out the *strongest* signal (which is a function of target gain, cross sectional area, and distance) or it can pick out the *fastest* signal. Note that these selections are relative — they are relative to what other vehicles are doing, what kind of vehicles they are, and their relative distances. Police radar cannot pick out the speed of the *nearest* vehicle. To make matters worse, one manufacturer has installed "gun sights" in an attempt to aid in target discrimination — the gun sights are useless. One manufacturer also allows the officer to "blank" out his/her own displayed speed in a moving mode, so as to not reveal to a potential violator that the officer was also violating the law.

In 1985, a paper was published in the Journal of Forensic Sciences, bemoaning the lack of *target specificity* with radar. In 30 years, little has changed. In an attempt to improve radar, the manufacturers have approached target speeds by using Fast Fourier Transform (FFT) spectral analysis, as opposed to analog Phase Lock Loop (PLL) techniques. The FFT technique, as does PLL usage, treats one target signal as "the" signal and processes the other return signals from other vehicles as if they were noise. In fact, this "noise" may represent the actual speed of the vehicle that is closest to the police car.

The attitude of some is that, "Well, it is only a traffic citation." In many cases, this is true. But some jurisdictions use strict traffic enforcement as the basis of *presumptive traffic stops* — they will issue a warning for the traffic violation and instead are looking for a reason to search a vehicle for contraband. This use of faulty radar as the basis for non-warranted traffic stops will also be explored.

Daubert, Traffic Radar, Doppler

Engineering Sciences Section - 2015

D28 Do I Really Have to Measure Everything Twice in My Forensic Investigation: Isn't Error Analysis Just Something One Does in Bench Science?

Thomas L. Bohan, PhD, JD*, MTC Forensics, 54 Pleasant Avenue, Peaks Island, ME 04108

After attending this presentation, attendees will be provided with an orientation to uncertainty estimates in the reporting of forensic conclusions and, in particular, to the talks immediately following which will explore the topic in detail.

This presentation will impact the forensic science community by providing one of the most important of the recommendations of the 2009 National Academy of Sciences (NAS) Report, *Strengthening Forensic Science in the United States: A Path Forward*, dealing with forensic practice in the United States.

This presentation leads off a half-day program examining the aspects of reliability analysis across a wide range of forensic practices. To set the stage for this program, it appears useful to lay out the reasons why such an examination is important so long after the NAS Report that sent shock waves through the public, this country's system of justice, and the forensic community. The shock came from the NAS Report's pointing to serious shortcomings in the practice of forensic science in this country. One of these shortcomings was the lack of appreciation the NAS Report's authors found of the importance of reliability analysis applied to stated forensic conclusions: "Few forensic science methods have developed adequate measures of the accuracy of inferences made by forensic scientists. All results for every forensic science method should indicate the uncertainty in the measurements that are made, and studies must be conducted that enable the estimation of those values."¹

This statement is embedded in several of the Report's thirteen recommendations, especially Recommendation 3 (Ibid, page 190.) Since the February 2009 issuance of the Report, the resolve within the forensic scientific community and within all three branches of the federal government to act has been mounting year by year. This reaction began within the American Academy of Forensic Sciences, which in August 2009, following Academy-wide consultations, endorsed all thirteen of the NAS Report's recommendations.

With all of the efforts expended, by forensic practitioners, by professional forensic organizations, and by the United States Congress and the White House, why is it still necessary to take time to address one of the most fundamental aspects of the NAS Report's observations, the need to report forensic results in such a manner that those receiving them can immediately grasp their reliability? Where the results are in numerical form (for example, the weight of a drug sample, the impact speed of a wrecked train, the relative humidity the night a crime took place), the reliability can be stated in terms of the likelihood that the number given could deviate by as much as plus or minus 10% from the true value. If that likelihood is very low, one might conclude that the result given was quite reliable, and conversely. Regardless of that likelihood, the conveyor of the number would have done his or her duty scientifically. If the numerical result is presented in naked form, with no "error bars," those receiving it have no way to weigh its importance and, in a scientifically ideal world, should not accept it.

But many forensic results (for example, the medical testimony that a deceased person died from a blow to the head) are not delivered in the form of a quantitative statement. Nevertheless, in addition to stating the basis for such qualitative conclusions, the person delivering them should be able to estimate the likelihood that he or she is incorrect. That is the way science must be done and forensic science should be no different.

Furthermore, as stressed by the NAS Report backed by the American Academy of Forensic Sciences through its 2009 Position Statement, if reliability estimates in a particular field are impossible or difficult to accomplish, the work necessary to correct this situation must be done and the results presented in the peer-reviewed literature.

The acceptance of the need to make quantitative reliability estimates varies across the forensic practice fields. For those that are specialized applications of a broader scientific tradition, the need to provide "error bars" with results has always been recognized. For those that originated with police practice, not so much. That there still exists resistance in some of the latter fields appears to result from two distinct problems. The easiest of these to deal with is actually one of the problems spotlighted by the NAS Report: the need to have a uniform nomenclature understood across all types of forensic practices. It should be added in connection with reliability estimates that there must be agreement across the practices as the words to be used with such estimates. It has been repeatedly noted that certain classes of practitioners strongly resist using such words as "error" and "uncertainty." Given the baggage that these words carry from the non-technical society, such resistance should not be criticized. Rather, there has to be a broad-based attempt to settle on words that convey what needs to be conveyed in the scientific context without at the same time smuggling in misleading meanings from the world at large.

Engineering Sciences Section - 2015

The other problem that needs to be overcome is a conceptual one. Most simply, it can be illustrated by the question: What relevance can studies of error over the last ten years across the entire field of handwriting identification have to assessing uncertainty in the work of a *specific* examiner in a *specific* case today? In order to achieve the goal of habituating all forensic practitioners to providing quantitative reliability estimates to all their conclusions, this question has to be answered in a convincing manner.

Reliability, Error Rate, Uncertainty

Engineering Sciences Section - 2015

D29 Error and Uncertainty in Toxicology and Drug Analysis — Terminology Matters

Suzanne Bell, PhD*, West Virginia University, Oglebay Hall, Rm 208, 1600 University Avenue, Morgantown, WV 26506-6121

After attending this presentation, attendees will understand the key differences in the terms “error” and “uncertainty” as applied in forensic science. The emphasis will be on quantitative methods used in forensic toxicology and seized drug analysis, but the concepts are generalizable to any quantitative measurement.

This presentation will impact the forensic science community by clarifying the definitions and proper use of these two terms (“error” and “uncertainty”) which are used to describe the utility and reliability of quantitative forensic data.

It is common for the term “error” to be used interchangeably with “uncertainty.” For informal conversation this is harmless; in forensic science this usage is misleading and potentially dangerous. The two terms are not synonymous and describe two fundamentally different properties associated with any quantitative measurement. While neither error nor uncertainty can be eliminated from any measurement process, it is possible to provide reasonable and defensible estimates of both quantities. Error is related to accuracy (how close is a given value to a true value?) while uncertainty is related to precision (how reproducible is a given result?). An estimate of uncertainty does not imply doubt or a poor measurement process. Rather, an uncertainty estimate improves the utility and reliability of any measurement. It is critical that forensic practitioners use these terms properly and convey the differences between these two words to stakeholders in judicial proceedings. This presentation will clarify the terminology and offer suggestions for explaining and presenting the differences to law enforcement and triers-of-fact. The emphasis will be on quantitative measurements obtained in forensic chemistry, but the concepts are generalizable to any quantitative measurement.

One of the challenges in the forensic context is defining what measurements are quantitative. This presentation will touch on this issue. For example, with searchable databases, a quantity is produced that expresses the closeness of agreement between a questioned and known exhibit. Thoughts to consider for such metrics will be introduced.

“Error” in a quantitative measurement refers to the difference between the reported measured value and the true value.¹⁻⁴ Given that the true value of any measurement is inherently unknowable, error is estimated using reference materials. Ideally, error values are obtained from a source such as the National Institute of Standards and Technology (NIST); examples are certified weights and standard reference materials such as ethanol in water. Uncertainty is defined as the range in which the true value is expected to lie. Uncertainty is reported along with a probability, usually stated as a confidence level. Both of these concepts will be defined and clarified using examples from seized drug analysis (reporting the weight of an exhibit) and forensic toxicology (blood alcohol analysis and postmortem drug concentration levels). Suggestions will be provided to illustrate how these concepts can be conveyed to judges and juries using everyday examples.
